concentrations measured in ice cores from the Dunde ice cap primarily reflect the influx of dust from the large desert basins (e.g., Taklamakan and Qaidam deserts) on the northern margin of the Tibetan Plateau. The glacial–interglacial transition is marked by a significant shift in many of the ice-core records. Holocene ice is characterized by a decrease in fine particles (<2 mm diameters), less negative $\delta^{18}\text{O}$, and an increase in soluble anions (chloride, nitrate, and sulfate). Enhanced dust deposition during the Late Glacial stage may have resulted from increased wind strength during this period, consistent with data from polar ice cores. The less negative $\delta^{18}\text{O}$ values suggest a shift to a warmer climate in the early Holocene, also consistent with other paleoclimate data. The increasing concentration of anions in the Dunde core during the Holocene suggests an increase of soluble aerosol originating from the Qaidam Basin, possibly a result of the formation and exposure of extensive evaporite deposits in the region, reflecting less precipitation and/or more evaporation in the late Pleistocene/early Holocene, although this cannot be verified by ice core accumulation time series as annual layers in the ice core could not be counted till 4.55 ka. Two of the three cores also show a trend to less negative $\delta^{18}\text{O}$ values over the last 60 years, suggesting a recent warming trend.

In 1992, a 309-m ice core was recovered from the Guliya Ice Cap, located in the West Kunlun Mountains (Thompson et al., 1997). Much of the ice recovered in the core appears to have accumulated since the beginning of the Pleistocene glaciation and provides details of the last glacial cycle in the western regions of the Tibetan Plateau. The $\delta^{18}\text{O}$ record from the Guliya core reveals a sequence of stadial and interstadial events similar to those recorded in polar ice cores and suggests that climate in this region was cool and variable during the last glacial cycle. In addition, between 25 and 33 ka, the $\delta^{18}\text{O}$ record contains abrupt high amplitude changes with an average length of 200 years; less negative $\delta^{18}\text{O}$ signals are associated with higher levels of dust, ammonium, and nitrate. These events are much shorter than the Dansgaard–Oeschger oscillations and may be related to short-term changes in snow-cover on the Tibetan Plateau. The transition from glacial to interglacial climate recorded in the Guliya core is not as sharp as the transition in polar ice cores, suggesting a slower change from glacial to interglacial climate in western China. Investigation of the stable isotope and calcium records suggests that the coldest periods in both the Guliya and Dunde ice cores occurred between AD 1000 and 1200. As was found in the Dunde ice core, the Guliya ice core revealed that the Little Ice Age was not as cold as expected. The Guliya $\delta^{18}\text{O}$ record also shows a trend toward less negative values over the last 200 years, suggestive of a region-wide warming trend (Thompson et al., 2003) and consistent with instrumental records of warming over the Tibetan Plateau over the past five decades (Liu and Chen, 2000).

Since 1997, many ice cores have been recovered from glaciers across central Asia. The locations of these new cores ranges from the eastern Himalayas to the central region of the Tibetan Plateau to the Altay in the north and to the Tien Shan in the northwest (Figure 3 and Table 2). This recent set of cores primarily provides records over the late Holocene; however, the relatively high accumulation rates allow for the development of high-resolution (i.e., annual to decadal) records of climate change over a broad region in central Asia.

Table 2 Chronological summary of ice cores (>70 years of record) that have been recovered from central Asian glaciers

Glacier	Elevation (m)	Latitude (N)	Longitude (E)	Maximum core length (m)	Age (years)	Year drilled	References

Himalayas

In the late 1990s, several cores were recovered from the central Himalayas in the Mt. Everest and Xixabangma regions (Figure 3 and Table 2) and provide records extending back hundreds of years. Cores recovered from the FER glacier in 1997 and the East Rongbuk (ER) glacier in 1998 have been analyzed for oxygen isotopes and a complete suite of major ions. Depth-age relationships were developed via counting of annual layers in the glaciochemical records, combined with identification of the 1963 and 1954 peaks in beta activity. Comparison of the two records suggests that the last 15 years of the FER may have been compromised as a result of increased ablation that coincides with a reduction in snow accumulation during the 1960s in the region (Qin et al., 2002; Thompson et al., 2000) and a rapid retreat of the ER glacier over the last 30 years (Qin et al., 2000). An increasing trend in sulfate, nitrate, calcium, and magnesium is apparent from the ER core beginning in the 1940s. The dominance of dust-related sources of major ions in this region (Wake et al., 2004) suggests that this increase reflects changes in atmospheric circulation and/or desertification in the region. The ER core also shows a doubling of ammonium over the last 50 years that likely reflects changes in anthropogenic activities, including enhanced agricultural activities in the region and atmospheric acidification (Hou et al., 2003; Kang et al., 2002c). Increasing temperatures in the southern regions of the Tibetan Plateau over the past several decades (e.g., Shrestha et al., 1999) may also have contributed to an increase in natural biological emissions of ammonia. Major ion records from both the ER and FER cores have been used to track interannual to decadal changes in atmospheric circulation in central Asia (Kang et al., 2002b; Wake et al., 2001). Increases in dust deposition over the past several decades in both cores record an intensification of winter circulation in central Asia.

More recently, a 1500-year record of the Asian monsoon has been developed from multiparameter analysis of a 108-m core on the ER glacier (Kaspari et al., 2007). Via comparison to NOAA National Centers for Environmental Prediction (NCEP) surface pressure records over the past 50 years, increases in calcium and decreases in sodium deposition over the last 400

years have been linked to an increase in the influence of continental air masses and decrease in the influence of marine air masses in the Himalayas. This, combined with a decrease in annual accumulation and increase in δD over the same time period, suggests a southward shift in the mean summer position of the inter tropical convergence zone over the past 400 years. High-resolution records of major and trace elements from the ER core show that concentrations and enrichment factors for bismuth, uranium, cesium, sulfur, and calcium have increased over recent decades, likely a result of increase in industrial activities and land use changes (Kaspari et al., 2009b). The major and trace element analyses also provide a record of variability in the amount and composition of dust deposited on the glacier (Kaspari et al., 2009a). Significant correlations of Everest dust concentrations with Total Ozone Mapping Spectrometer aerosol index during the winter (December, January, February) suggest that the dominant winter sources of dust are the Arabian Peninsula, Thar Desert, and northern Sahara. While the record was examined for recent increases in dust deposition associated with anthropogenic activities, no conclusive relationship was found. Temporal variations in the number and size of insoluble particles over the past 500 years were used to examine a link among the NAO (a proxy for strength of westerly circulation), precipitation and accumulation in central Asia, and dust deposition during the spring (Xu et al., 2009). Hong et al. (2009) developed an 800-year record from the ER core of select trace elements that show pronounced increase in levels of arsenic, molybdenum, tin, and antimony over the past century, which they link to rising levels of atmospheric pollution in response to rapid economic growth in central Asia.

A 168-m core recovered from Dasuopu glacier on Mt. Xixabangma in 1997 provides a record extending back 1000 years (Thompson et al., 2000). Peaks in the dust and chloride records in 1876–77 and 1790–96 are thought to represent reductions in the intensity of the summer monsoon that resulted in devastating drought across much of India and considerable loss of life. The 1876 signal was also observed in the ER core (Hou et al., 2003). The Dasuopu core also shows recent increases in dust, nitrate and, sulfate that are attributed to increased aridity, increased agricultural activity, and/or

increasing temperatures in the region. The oxygen isotope record also shows a trend to less negative values over the past 200 years. Based on comparison of this increasing trend with similar trends in oxygen isotope records from the Guliya and Dundee cores, and with similar trends in Northern Hemisphere temperature records, Thompson et al. (2000, 2003) have interpreted the Dasuopo oxygen isotope record as a proxy for increasing temperatures in the region (Figure 6). However, observational and modeling studies focused on the $\delta^{18}\text{O}$ signal in Himalayan precipitation have repeatedly concluded that the amount effect exerts significant control on the seasonal variation in stable isotope ratios in precipitation in the region, with the most isotopically depleted precipitation (and therefore most negative $\delta^{18}\text{O}$ values) in summer monsoon-derived precipitation (Araguas-Araguas et al., 1998; Hoffman and Heinmann, 1997; Tian et al., 2003). These studies also show that the temporal variability in stable isotopes in Himalayan precipitation is influenced by a complex set of processes involving changes in the sources of moisture, changes in atmospheric transport histories, and changes in temperature. This will require additional field and modeling studies to better decipher the climatic signals preserved in stable isotope records from Himalayan glaciers. The increasing trend in $\delta^{18}\text{O}$ recorded in Himalayan cores (Dasuopo, ER) over the past several decades does, however, indicate that rising temperatures in the region identified from instrumental data (Shrestha et al., 1999) are, not surprisingly, linked to changes in the regional hydrological cycle. Davis et al. (2005) investigated relationships among recent snow accumulation and $\delta^{18}\text{O}$ records from the Dundee and Dasuopo, the NAO, monsoon-derived precipitation records, and Northern Hemisphere temperature records. They concluded that increased snow accumulation during the latter stages of the Little Ice Age in central Asia was influenced by North Atlantic and Eurasian sources of moisture, while there has been a greater tropical influence on snow accumulation since 1880.

Central Tibetan Plateau

Preliminary results are available from several of these ice cores. The upper 24 m of the 102 m Malan ice core has been dated, providing a 112-year stable isotope record that reflects changes in summertime temperatures in the region (Wang et al., 2003).

Comparison of the stable isotope record with indices representing the NAO and SO suggests that warm season air temperatures over the Tibetan Plateau are influenced by the phase and strength of NAO and SO, most likely via changes in the strength of westerlies and the Indian monsoon, although the lack of any supporting analysis of regional meteorological data makes the results speculative.

New ice cores recovered from the Puruogangri Ice Cap in the central region of the Tibetan Plateau provide a record extending back through the mid-Holocene (Thompson et al., 2006). The record since ~1920 suggests a warmer and wetter climate in the central region of the Tibetan Plateau. The longer term record shows several events of high dust and major ions over the past 7000 years and a significant increase in calcium at 1200 years before present. The latter likely reflects local environmental changes. Analysis of changes in accumulation recorded in ice cores on a southwest-to-northeast transect across the Tibetan Plateau from the eastern Himalayas to the Dundee ice cap show a broadly consistent regional pattern of gradual decrease in accumulation over two to three centuries followed by an increase beginning in the late 1800s/early 1900s, and then a decrease in the 1990s (Kaspari et al., 2008).

A 70-year soluble ice-core dust record from the north side of Mt. Geladaindong in the central Tibetan Plateau suggests a teleconnection between dust deposition in central Asia and the Pacific Decadal Oscillation (PDO), as a threefold decrease in dust concentrations coincides with the 1976–77 shift in the PDO (Grigholm et al., 2009). Kang et al. (2010) linked the shift in dust deposition in the 1970s recorded in the Geladaindong core to a strengthening of atmospheric circulation over the Tibetan Plateau.

A 131 m surface-to-bedrock core was recovered from Mt. Tanggula (adjacent to Mt. Geladaindong) in 2005. The upper 14.5 m spans a period from 1950 to 2004 shows an increase in sulfate, nitrate, and ammonium that are attributable to anthropogenic emissions and increasing temperatures enhancing biological activity (Zheng et al., 2010).

Altay, Pamirs, and Tien Shan

The upper 86 m of a 140 m core from the Belukha glacier in the Altai provides a record extending back two centuries (Olivier et al., 2003, 2006). Ammonium and formate time series

Figure 6 Decadal averages of $\delta^{18}\text{O}$ values for the last millennium from three Tibetan ice cores (Dunde, Guliya, and Dasuopo; Thompson et al., 2003).

provide a record of Siberian forest fire activity (no trends). Sulfate shows a sharp increase after 1950 that peaked in 1970, and then decreased during the 1980s, reflecting variations in sulfur dioxide emissions in Siberia and Kazakhstan. Rising nitrate concentrations since 1960 reflect emissions from motor vehicles and/or enhanced fertilizer production, while rising ammonium since 1950s is related to enhanced agricultural activity. Analysis of large samples from the upper portions of the core has provided a record of global fallout of plutonium over the past five decades (Olivier et al., 2004). Henderson et al. (2006) found no long-term trends in accumulation in the Belukha ice-core record, but did suggest that the two temperature proxies ($\delta^{18}\text{O}$ and melt percent profiles) show strong warming over the past century. Okamoto et al. (2011) developed a record of summer temperature via analysis of melt features and annual accumulation on the upper 48 m of a second ice core retrieved from Mt. Belukha in the Siberian Altai mountains. The ice-core record shows substantial increase in summertime temperatures that began in the 1980s.

Three ice cores have been recovered from the Inylchek glacier in the Tien Shan in Kyrgyzstan. Preliminary analysis shows significant interannual variability in dust deposition during the 1990s as well as a strong anthropogenic ammonium signal, while deuterium excess displays a strong seasonal cycle related to seasonal changes in the moisture sources, transport history, and moisture recycling in the Caspian/Aral Sea region (Kreutz et al., 2003). Analyses of major element, rare earth element, and stable isotopes ($\delta^{18}\text{O}$ and $\delta^{34}\text{S}$) indicate three distinct sources for dust (loess, calcium carbonate, and gypsum) and two distinct sources for sulfur (evaporite deposits and anthropogenic emissions; Kreutz and Sholkovitz, 2000; Preutt et al., 2004). Analysis of the amount of summer melt in the ice core (as determined by the amount of clear ice) indicates a significant increase in surface melting over the past few decades, consistent with observations of retreating glaciers in the Tien Shan over the years.

A 90-year record of major ions developed from a 55 m core recovered from Mt. Mustagata in the Pamirs shows an increase in sulfate and nitrate since the late 1970s suggesting an anthropogenic source (Zhao et al., 2011). Analysis of heavy metals on a separate core from Mustagata shows an increase in antimony and bismuth in the 1960s, followed by a decrease in the late 1990s (Li et al., 2006). These trends were linked to changes in anthropogenic activities in central Asia.

Preliminary results from glaciochemical analysis of snowpit and shallow core samples from the Fedchenko glacier in the Pamir (38.25° N, 72.25° E) show well-defined seasonal layering appearing in stable isotope and trace element content, suggesting the potential for developing a deep core from this site in the future (Aizen et al., 2009).

Final Comments

Analysis of the chemical and physical characteristics of ice cores recovered from several different glaciers in the mountains of central Asia over the past 25 years have significantly improved our understanding of climatic and environmental change in the region. These ice-core records have documented oscillations in the climate system on several different

timescales, identified abrupt changes in the climate system, revealed recent warming trends and changes in the hydrological cycle, and documented the influence of anthropogenic emissions on precipitation chemistry. Several new ice cores have been recovered over the past decade that provide additional details on the spatial and temporal variability of the Asian monsoon and the westerly jet stream, and additional records detailing the anthropogenic influence on atmospheric chemistry in this remote region. Despite this, there remain considerable gaps in our understanding of the regional details of climate change in this vast area. Detailed synthesis of existing records (e.g., Kaspari et al., 2008) are required to better understand the spatial and temporal changes in the environment and climate of this vast region. Additional ice cores will be required to fill in these details. However, the recent warming across much of the region, recorded in instrumental and ice-core records and evidenced by retreating glaciers, indicates that time is of essence. Many of the unique archives locked up in central Asian glacier ice appear destined to disappear in a world warmed by anthropogenic greenhouse gases.

Introduction

Tropical and subtropical glaciers are restricted to high mountains in the Andes, on the Tibetan Plateau, in East Africa, and in a few isolated locations. Currently, ~500 000 km² of the world's ice is frozen in glaciers and ice sheets outside the polar regions (Benn and Evans, 1998). Although the tropics (30° N to 30° S) contain only a fraction of all the Earth's ice, they encompass 50% of the Earth's surface area and are home to 70% of the world's inhabitants. In regions such as the Andes of South America, populations are critically dependent on these glaciers, as they are the source of water for agriculture and hydroelectric power.

Many of the measurements made on polar ice cores are also performed on cores from the Andean mountain glaciers. Researchers can utilize an ever expanding ice-core database of multiple proxy information (i.e., stable isotopes, insoluble dust, major and minor ion chemistry, precipitation reconstruction) that spans the globe in spatial coverage and is of the highest possible temporal resolution. These parameters potentially can yield information on regional histories of variations in temperature, precipitation, moisture source, aridity, vegetation changes, etc. Many of these physical and chemical constituents have wet and dry/cold and warm seasonal signals in the ice, which allow the years to be counted, much as tree rings.

The ice-core records from the Earth's Alpine ice caps and glaciers provide a wealth of data that contribute to a spectrum of critical scientific questions. These range from the reconstruction of high-resolution climate histories to help explore the oscillatory nature of the climate system, to the timing, duration, and severity of abrupt climate events, to the relative magnitude of twentieth-century global climate change and its impact on the cryosphere. The longest of these records have revealed the nature of climate variability since the Last Glacial Maximum (LGM), 18 000 to 20 000 years ago, and even beyond. The more recent sections, which are of annual and even seasonal resolution, have yielded data on the temporal variations in the occurrence and intensity of coupled ocean-atmosphere phenomena of global significance such as El Niño, which are most strongly expressed in the tropics. This is particularly valuable information since meteorological observations from much of this region are scarce and of short duration.

The History of Ice-Core Drilling in the Andes

Glaciological and ice-coring programs have been conducted throughout the Andes for over three decades (Table 1). Figure 1 illustrates the sites in Peru and Bolivia from where the longest ice-core records have been obtained. The earliest efforts to retrieve climate records from mountain glaciers included programs from 1974 to 1979 involving surface sampling on the

Quelccaya ice cap (13° 56'S, 70° 50'W; 5,670 m above sea level, or m a.s.l.) in southern Peru (Thompson et al., 1979). The results from this preliminary research, conducted by the Institute of Polar Studies (now the Byrd Polar Research Center, or BPRC) at The Ohio State University, paved the way for the first tropical high-altitude deep-drilling program on Quelccaya in 1983, which recovered two cores to bedrock that yielded precisely-dated, annually-resolved 1500-year climate records (Thompson et al., 1985; 1986). The Quelccaya program marked a series of 'firsts' in the history of ice-core drilling, in that it produced the first long high-altitude cores from the tropics, and was the first in which solar power was exclusively used for drilling (Figure 2).

The 1990s was a decade of increased ice drilling activity in the central Andes. In 1993, two cores were drilled to bedrock in the col of Nevado Huascarán (9° 07'S, 77° 37'W, 6050 m a.s.l.) in the Cordillera Blanca range of northern Peru. The climate records from these cores extend back to 19 000 years to the end of the LGM, and provided the first glacier evidence of substantial ice-age cooling in the tropics (Thompson et al., 1995). Four years after the Huascarán program, the summit of Nevado Sajama (18° 06'S, 68° 53'W, 6540 m a.s.l.), an extinct volcano on the Bolivian Altiplano, was drilled. The two cores drilled to bedrock provided a 25 000-year climate history, which confirmed the ice-age cooling in the tropics that was seen in Huascarán (Thompson et al., 1998). The time series from Sajama was the first to be reconstructed from an ice core with the aid of radiocarbon (¹⁴C) dates. In 1999, the Institute of Research and Development (IRD) in France led an effort to recover two cores from the Illimani ice cap (16° 37'S, 67° 47'W, 6350 m a.s.l.), which like Huascarán and Quelccaya, is located along the eastern edge of the Andes. The record from this glacier also extends back to the end of the last glacial stage (Ramirez et al., 2003).

In 2003, two decades after it was first drilled, a second program on the Quelccaya ice cap resulted in the recovery of two cores to bedrock on adjacent domes. That same year three cores were retrieved from Nevado Coropuna, located in the Western Andean Cordillera (15° 32'S, 72° 39'W). Cores 1 and 2 were drilled on the crater rim at the summit, while Core 3 was drilled in the central crater (Table 1). These records are currently being developed.

The Physical and Meteorological Setting of Tropical South America

The topography and meteorology of tropical South America have strong influences on the climate record preserved in the Andean ice cores. Although the South American continent covers 68° of latitude between 12° N and 56° S and encompasses a variety of climatic regimes from tropical rainforest in

Table 1 Ice-cores sites in the Peruvian and Bolivian Andes

Site name	Location	Elevation(m asl)	Year drilled	Annual net accumulation m water eq.	Depth of boreholes (m)	Length of record (yrs)
Huascarán	9°06'S, 77°37'W	6050	1993	1.3	160, 166	19 000
Quelccaya	13°56'S, 70°50'W	5670	1983	1.4	155, 164	1500
			2003		170, 129	
Illimani ^a	16°37'S, 67°47'W	6350	1999	0.58	137, 139	18 000
Coropuna	15°32'S, 72°39'W	6425	2003	0.50	34, 34, 146	To be determined
Sajama	18°06'S, 68°53'W	6540	1997	0.44	132, 133	25 000

Synopsis of the major ice-core drilling programs in the South American Andes Mountains. All the cores listed were drilled and analyzed by the Byrd Polar Research Center at the Ohio State University with the exception of Illimani^a, which was drilled and analyzed for isotopes by the Institute of Research and Development (IRD) in France (Ramírez et al., 2003). Analysis of the Quelccaya and Coropuna cores drilled in 2003 are currently underway.

the north to polar tundra at its southern tip, its meteorology is simpler than expected for so large a landmass. Because it is much longer than it is wide and is virtually surrounded by oceans, it is highly affected by surrounding maritime air masses and pressure systems. The most prominent physical features include the Andes Mountain complex that runs along the length of the continent parallel to the west coast, the Amazon Basin which covers most of the central region north of 10°S, and the high (3500 to 4000 m a.s.l), arid Altiplano of southern Peru and Bolivia. From 15°S to 22°S, the Altiplano divides the Andes into the main range of the Cordillera Occidental to the west and the Cordillera Central to the east.

The Andes Mountains and the Amazon rainforest are especially vital influences on South American climates and environments. The extensive meridional length and the great altitude of the Andes are responsible for the division of

the subtropical high-pressure belt in the Southern Hemisphere into two major cells that flank the continent on both the Pacific and Atlantic sides. From December to February (the austral summer), these cells strengthen and move slightly southward (Figure 3a). A summertime thermal low, called the Chaco Low, develops in the center of the continent as an extension of the southward-dipping equatorial trough. During the austral summer, which is also the wet season in the Amazon Basin and along the eastern flanks of the Andes, the equatorial trough dips to 25° S and the northeasterly trade winds are channeled into the continental interior by the southern limb of the Azores high-pressure cell in the subtropical North Atlantic. The vegetation in the Amazon rainforest recycles moisture that is carried by the trade winds as they move across the continent to the Andes. An upper level closed anticyclone, the Bolivian High (not shown), also forms during

the summer as a result of latent heat release over the Amazon Basin (Lenters and Cook, 1997).

In the austral winter (June to August), the equatorial trough moves northward to around 10° N, and the circulation around the South Atlantic high-pressure system becomes more dominant (Figure 3b). The South Pacific and South Atlantic high-pressure cells weaken and move slightly to the north, and the high-pressure systems in the Northern Hemisphere strengthen and move northward along with the equatorial trough. Thus, moisture from the North Atlantic is effectively blocked to the northern interior of the continent. The Bolivian High and the Chaco Low disappear in the winter, and northerly winds diminish over the Amazon Basin and the northern and central Andes.

Subsiding air from the South Pacific high pressure system, along with a northward advecting cold water current along the coast, produce stable, dry conditions along the west coast from 30° S to 14° S. The result is the Atacama Desert of Northern Chile and Southern Peru, one of the driest places on Earth (Vuille and Ammann, 1997). South of ~20° S the prevailing westerly winds dominate upper and lower tropospheric circulation throughout the year, and they channel 'cut-off lows' (Vuille, 1999; Marengo and Rogers, 2000) that provide the coastal areas with a humid climate, while on the lee side of the mountains the land is dominated by the Patagonian desert in southern Argentina.

Precipitation over Tropical South America

The ultimate source for the precipitation that falls on the central and northern Andes is the subtropical North Atlantic Ocean (Taljaard, 1972; Grootes et al., 1989) via the Amazon Basin. Precipitation in the Amazon is strongly influenced by the strength and position of the Intertropical Convergence Zone/equatorial trough (ITCZ/ET) and by the Azores high-pressure system (Figure 3a), which advects maritime tropical air westward in a shallow, cool, and humid layer. In the austral summer, when the equatorial trough is at its southernmost position around 25° S over the continent, this shallow layer encounters the Chaco Low just to the east of the Andes (between 15 and 30° S and 60 to 68° W) and rises to ~4000 m a.s.l., resulting in humid, unstable air masses that diverge at the 500-hPa level. The upper level air flows westward over the Andes, releasing large amounts of precipitation through convection. The water vapor that travels from the Atlantic accounts for only part of the rainfall over the Amazon Basin (Marques et al., 1977), and much of the remainder is supplied by evapotranspiration of the vegetation over the rain forest canopy. Although November to April is the wet season in the southern tropics of South America, some snow also falls in the winter in the northern and central Andes, but the precipitation is sporadic and is the product of local orogenic effects.

Stable Isotopic Ratios of Oxygen ($\delta^{18}\text{O}$) in Andean Ice Cores

Isotopic ratios of oxygen ($\delta^{18}\text{O}$) and hydrogen (δD) in water are among the most widespread and important of the measurements made on ice cores (see Stable Isotopes). The information provided by $\delta^{18}\text{O}$ and δD is based on the fractionation of the oxygen and hydrogen atoms, respectively, into

Figure 3 Major surface pressure cells and prevailing winds (shown by open arrows) over South America and the adjacent oceans for (a) December to March (the austral summer) and (b) June to September (the austral winter). Sea level pressure values are in hectopascals (hPa), the metric equivalent of millibars. The shading over the North Atlantic illustrates regions in which the northeasterly trade winds dominate the surface air circulation.

their light and heavy isotopes (^{16}O and ^{18}O , H and ^2H) and on the higher vapor pressure of H_2^{16}O over H_2^{18}O , and $^2\text{H}_2^{16}\text{O}$. Early work on these 'stable' (i.e., as opposed to unstable, or radioactive) isotopes in polar ice cores resulted in the development of transfer functions between the isotopic ratios and the water temperature at the moisture source and the atmospheric temperature as the water vapor condenses into precipitation (Dansgaard, 1964). The use of $\delta^{18}\text{O}$ as a temperature proxy for polar ice is now widely accepted, but is, however, still a source of controversy for low-latitude cores. Some who have studied the problem believe that it is precipitation, rather than temperature, that exerts the strongest influence on $\delta^{18}\text{O}$ in the tropics (Rozanski et al., 1993; Baker et al., 2001), while others contend that temperature is the dominant factor, at least over intra-annual and longer timescales (Thompson et al., 2003).

The relatively large annual accumulation rates and the high-resolution sampling of the ice cores from two of the Andean sites, Huascarán and Quelccaya, allow wet/dry season partitioning of the dust and oxygen isotopic records. Dust and other aerosols such as salts are concentrated in the dry season (austral winter) layers and, in contrast to polar ice-core records, the summer snow is depleted in ^{18}O (resulting in more negative $\delta^{18}\text{O}$ values). A model by Grootes et al. (1989) presents a possible mechanism for this summertime isotopic depletion, which involves biological (evapotranspiration) processes over the Amazon Basin and adiabatic cooling during the uplift of air when it comes in contact with the Andes.

The Atlantic influence on interannual variations in $\delta^{18}\text{O}$

The spatial distribution of sea surface temperature anomalies (SSTAs) in the western tropical Atlantic has an effect on the oxygen isotopic fractionation in precipitation via the strength of the 500-hPa zonal easterlies over the Amazon Basin (Henderson et al., 1999). More enriched isotopes in the Huascarán record correspond to lower Azores sea-level pressure (SLP), and they are linked through the influence of the strength of the NE trade winds that compose the southern limb of that high pressure cell. During austral summers in which the Atlantic ITCZ is weaker than average, the precipitation tends to be less ^{18}O -depleted (i.e., higher $\delta^{18}\text{O}$ values). In the equatorial Atlantic the austral summer SLPs are positively correlated with the wet season $\delta^{18}\text{O}$, meaning that more ^{18}O -enriched water vapor occurs with higher SLPs in this low-pressure zone. A weaker equatorial low implies weaker low-level convergence and less convective precipitation that is channeled into the Amazon Basin, leaving the isotopic composition of the water vapor over the rainforest more influenced by the unfractionated product of evapotranspiration and resulting in a trend toward ^{18}O enrichment.

All these mechanisms combine into a reasonable model that links the Azores high pressure system with the isotopic composition of the precipitation over the Andes between 9°S and 14°S . Weaker 500-hPa easterlies and reduced precipitation in the northern Amazon Basin and northern Peru tend to be consequences of strong El Niño Southern Oscillation (ENSO) events, and less isotopic fractionation of the prevailing air masses results in ^{18}O -enriched precipitation that ultimately falls on the Andes glaciers. Several studies in addition to Henderson et al. (1999) show that there is a tropical Atlantic

sea surface temperature analog to the ENSO patterns in the Pacific (Weare, 1977; Hastenrath, 1978; Lough, 1986; Servain and Legler, 1986; Servain, 1991).

Climate Records from Andean Glaciers

Millennial-Scale Variations

Three of the records from the Andes (Huascarán in northern Peru and Sajama and Illimani in Bolivia, Figure 4a) extend to the last glacial stage and confirm, along with other climate proxy records (Stute et al., 1995; Guilderson et al., 1994), that the LGM was much colder in the tropics and subtropics (Thompson et al., 1995; Thompson et al., 1998; Ramirez et al., 2003) than previously believed (CLIMAP, 1976). Although this period was consistently colder, it was not as consistently arid throughout the lower latitudes as it was in the polar regions. For example, the dust records from Huascarán and Sajama (Figure 4b) indicate that the effective moisture (precipitation minus evaporation) along the axis of the Andes Mountains during the LGM was variable, being much drier in the north (as suggested by the high dust concentrations in the early part of the Huascarán record) than in the Altiplano region in the central part of the range (shown by the low dust concentrations in the Sajama ice-core record).

Ice cores from the Andes can also contribute to our understanding of past environmental and climatic conditions in the Amazon Basin. The extent of biological activity in the Amazon rainforest during the LGM is controversial (Colinvaux et al., 2000), and the nitrate concentration record from the Huascarán ice core (Figure 4c) has been cited in the argument (Thompson et al., 1995). Pollen studies from the Amazon Basin suggest that the extent of the rainforest has not changed much between the LGM and the Holocene, however, proponents of the 'refugia' theory (Clapperton, 1993) assert that the cold, dry climate in the tropics caused a major retreat of the rainforest flora into small, geographically isolated areas, leaving most of the Basin covered by grasslands. In the Huascarán record, the nitrate concentration profile is similar to that of the $\delta^{18}\text{O}$ throughout most of the record (Figures 4a, and c), and the very low concentrations of nitrate that are concurrent with very depleted $\delta^{18}\text{O}$ suggest that biological activity upwind of the Cordillera Blanca was impeded by the cold and dry climate $\sim 19\,000$ years ago. Nitrate variations in the Sajama ice core record also reflect changes in effective moisture, however, the link is through aerosols derived from the numerous salars (salt deposits) on the Altiplano, rather than just through biological emissions.

Many of the deep cores from the low latitudes that extend through the Holocene show spatial variations in climate, even between records from the same region. For example, the Holocene stable isotope from Huascarán and Illimani, while similar to each other in that they show early Holocene isotopic enrichment, are different from the Sajama isotopic record, which shows little trend through the last 10 000 years (Figure 4a). Although Sajama and Illimani are geographically close to each other, they lie on opposite sides of the Andes Mountains, with Illimani located in the eastern range. Like Huascarán far to the north, it has received most of its precipitation from the northeast after it has been recycled through the Amazon Basin. Sajama, which is located on the high, dry

Figure 4 Long-term records of (a) stable isotopic ratios from the Huascarán, Illimani, and Sajama ice cores, (b) concentrations of dust (0.63 to 16.0 microns in diameter) from Huascarán and Sajama, and (c) concentrations of nitrate in the Huascarán and Sajama ice cores. The Huascarán and Sajama records are shown as 100-year averages. The Illimani δD record is adapted from [Ramírez et al. \(2003\)](#), with permission.

Altiplano, is more subject to Pacific influences and local hydrological effects. Also, because its precipitation rate is much lower than that for the eastern Andes cores ([Table 1](#)), it is more prone to snow sublimation at the glacier surface, which contributes to isotopic enrichment.

The existence of high-altitude glaciers from glacial to interglacial stages has struck a balance between temperature and orbital precession-driven precipitation ([Thompson et al., 2005](#)). The ice cap on top of Nevado Sajama began to grow $\sim 25\,000$ years ago in response to insolation-driven precipitation, although the temperatures remained cold. The ice on Nevado Huascarán, 1370 km to the northeast on the east side of the Andes, began to grow $\sim 19\,000$ years ago,

about 6000 years after the beginning of the formation of the Sajama ice cap. Approximately 23 000 years ago summer insolation had just reached its maximum at 9°S and precipitation intensity was beginning to increase from the LGM aridity in the tropical latitudes. At the time that Huascarán began to grow, precipitation over the Altiplano where Sajama is located was at its highest since the LGM ([Thompson et al., 1998](#)). Unlike the glaciers on Huascarán and Sajama, which are frozen to the bedrock, the base of the much lower Quelccaya ice cap is at the pressure melting point. Thus, thousands of years of the ice-core record have been removed from the bottom, leaving only a 1500-year climate history.

Century-Scale Variations

Abrupt climate events

Holocene ice-core records from mountain glaciers around the world show evidence of major climatic disruptions such as droughts and abrupt cold events during this period, which previously was believed to have been stable. A major dust event beginning between 4200 and 4500 years ago and lasting several hundred years is observed in the Huascarán record (Figure 4b), and its timing and character are similar to drought-related signals seen in a marine core record from the Gulf of Oman (Cullen et al., 2000) and a speleothem $\delta^{13}\text{C}$ record from Israel (Bar-Matthews et al., 1997). This dry period is also documented in several other proxy climate records throughout Asia and Africa (Dalfes et al., 1997; Thompson et al., 2002), and its occurrence in those regions and in tropical South America may have been due to a prolonged period of anomalously frequent and/or intense ENSO conditions (Davis and Thompson, 2006).

Several short-term dry periods are visible in the Sajama dust and nitrate records (Figures 4b, and c) after about 5500 years ago. Other proxy climate data from South America (Rodbell et al., 1999) and Australasia (Schulmeister, 1999) suggest that it was at this time in the middle Holocene that the frequency and/or intensity of El Niño increased from early Holocene levels. Garreaud and Aceituno (2001) explained the relationship between interannual variation in precipitation over the Altiplano and ENSO by linking the warming of the tropical troposphere during the negative phase of ENSO with the strengthening of the westerlies, which sets up lower precipitation and more arid conditions. If this relationship between Altiplano aridity and ENSO holds true, then the Sajama aerosol records also confirm this middle Holocene change in tropical oceanic/atmospheric coupling.

The 'Little Ice Age'

High-frequency climatic variations over the last millennium are recorded in decadal averages of $\delta^{18}\text{O}$ from the Quelccaya ice core (Figure 5a), which unlike the other records is annually dated back 1500 years (Thompson et al., 1985). From these

records came some of the first evidence for a Southern Hemisphere climatic cooling, indicated by lower $\delta^{18}\text{O}$, from the mid-fifteenth century to the mid-nineteenth century (Thompson et al., 1986). This was coincident with the 'Little Ice Age' previously seen in other parts of the world, as discussed in several papers in Bradley and Jones (1992). The reconstructed net accumulation rate (a indicator of snow precipitation) fluctuated widely during this period (Figure 5b), increasing to a maximum in the mid-seventeenth century, then decreasing rapidly to a minimum that persisted from the mid-eighteenth to the mid-nineteenth centuries. This changing relationship between $\delta^{18}\text{O}$ and the accumulation is at odds with the argument that stable isotopes in the tropics are primarily influenced by precipitation amount over decadal and longer time scales. If this were the case, the net accumulation would be consistently higher in that part of the record corresponding to the Little Ice Age, when $\delta^{18}\text{O}$ is consistently lower.

The Modern Climate Warming and its Effects on the Andes Mountain Glaciers

Meteorological data from around the world suggest that the Earth's globally averaged temperature has increased 0.6°C since 1950. The El Niño year of 1998 saw the highest globally averaged temperatures on record, while 2002 (a non-El Niño year) was the second warmest, followed by 2003 and then 2004 (a La Niña year). The recent warming of the past century, which has been accelerating in the last two decades, is recorded in alpine glaciers both within the ice-core records and by the rapid retreat of many of the ice fields themselves. In the Andes this climate change has left its mark. The twentieth-century shrinking of the Andean ice fields, when placed within a maximum 25 000-year perspective provided by the ice core records, shows that the current wasting of these ice fields is unprecedented in the Holocene despite evidence of intense and abrupt climatic disruptions in the past.

The ongoing retreat of Andean glaciers is now well-documented (Ames, 1998; Thompson et al., 2003; Thompson, 2004) and can be placed within a longer time perspective.

Figure 5 Decadal averages from AD 500 to 1980 from the Quelccaya ice-core record of (a) oxygen isotopic ratios and (b) reconstructed net accumulation, a proxy for precipitation. The blue bar outlines the 'Little Ice Age'.

Figure 6 Photographs of the Qori Kalis outlet glacier on the Quelccaya ice cap. Between (a) 1978 and (b) 2005 the glacier has retreated 1100 meters.

The retreat of Qori Kalis, the largest outlet glacier from the Quelccaya ice cap, has been studied by terrestrial photogrammetry since 1978 and is the best documented recent history of any tropical glacier (Figure 6). The rate of its retreat from 1983 to 1991 (14 m/yr) was more than two times that between 1963 and 1983 (6 m/yr), and in the 2000/2001 year it reached 205 m/yr. There were periods when the retreat actually stopped (1991 to 1993 and 2002 to 2003) only to resume again in subsequent years. Overall, the rapid and accelerating wastage, in which the glacier front was receding between 1991 and 2005, was about 10 times faster than it was during the initial measurement period from 1963 to 1978.

This warming in the Andes is affecting the climatic signals in the ice-core records. The distinct seasonal oscillations in $\delta^{18}\text{O}$ that were visible at the top of the Huascarán ice cores (6050 m a.s.l.) in 1993 were obliterated by percolating meltwater in nearby, lower-elevation glaciers in the Cordillera Blanca such as Hualcán (5250 m a.s.l.), Pucahirca (5120 m a.s.l.), and Copap (5060 m a.s.l.) (Davis et al., 1995). The rate of melting is very fast; for example, the seasonal signals that were visible in the top of the Pucahirca glacier in 1984 were completely smoothed by 1990.

Future Priorities

Ice cores from mountain glaciers, especially those from the tropical latitudes where most of the world's population is concentrated, provide unique and valuable archives of climate

information because they are able to record variations in atmospheric chemistry and conditions. Since 1982, the ENSO phenomenon has gained worldwide attention as populations and governments have come to realize the extent of its widespread and often devastating effects on weather. As we begin to understand how this coupled atmospheric-oceanic process works, we also see its linkages with other important systems such as the Asian/African monsoons. Because both of these tropical systems influence precipitation and temperature over large regions, their effects are also recorded in the chemistry and the net accumulation of snow that falls on alpine glaciers. Seasonal and annual resolution of chemical and physical parameters in ice-core records from the Andes Mountains have allowed reconstruction of the variability of the ENSO phenomenon over several hundred years (Thompson et al., 1992; Henderson et al., 1999). Because the effects of El Niño and La Niña events are spatially variable, future ice core records from the northernmost (Columbia) and southernmost (Patagonia) reaches of the Andes Mountains will help further resolve their frequency and intensity, along with temperature variations long before human documentation. This will aid in placing the modern climate changes and the modern ENSO into a more comprehensive perspective.

At this time all the Earth's mountain glaciers are in retreat (Meier et al., 2003), a process which in many places has been accelerating over the past few decades. This has been linked to a marked and sustained rise in the global temperatures since the 1970s that has been superimposed on the more gradual warming that has occurred over the twentieth century. Some of the most dramatic evidence for the major climate warming that is underway today comes from the drastic decrease in both total area and total volume of the mountain glaciers. This rapid retreat causes concern for two reasons. First, these glaciers are the world's 'water towers', and their loss threatens water resources necessary for hydroelectric power production, crop irrigation, and municipal water supplies for many nations. The ice fields constitute a 'bank account' that is drawn upon during dry periods to supply populations downstream. The current melting is cashing in on that account, which was built up over thousands of years but is not currently being replenished. The second concern that is brought about by the disappearance of these ice fields is that they contain paleoclimatic histories that are unattainable elsewhere, and as they melt, the records preserved within them are lost forever. These records are needed to discern how climate has changed in the past in these regions and to assist in predicting future changes.

This article is a revision of the previous edition article by J. Jouzel, V. Masson-Delmotte, volume 2, pp. 1242–1250, © 2007, Elsevier B.V.

Introduction

An intensive monitoring of precipitation isotopic composition has been operating since the 1950s (e.g., Dansgaard, 1953). Natural waters formed mostly of H_2^{16}O molecules (99.7%) also exhibit less frequent stable isotopic forms, including about 0.2% of H_2^{18}O and 0.03% of HD^{16}O (D stands for deuterium ^2H). Isotopic concentrations are expressed in per mil δ units (δD and $\delta^{18}\text{O}$) with respect to Vienna standard mean ocean water (V-SMOW) (the Vienna standard mean ocean water, with D/H and $^{18}\text{O}/^{16}\text{O}$ atomic ratios of 155.76×10^{-6} and 2005.2×10^{-6} , respectively).

Measurements of modern precipitation revealed the potential of past precipitation for reconstructing paleoclimatic changes, owing to the existence of a relationship between δD or $\delta^{18}\text{O}$ and surface temperature at the middle and high latitudes. This relationship is very consistent and linear over Antarctica with an isotope content/surface temperature slope of $\sim 6\text{‰}/\text{C}$ for δD and of $\sim 0.75\text{‰}/\text{C}$ for $\delta^{18}\text{O}$ (Lorius and Merlivat, 1977). This ice sheet, which offers the widest reservoir of preserved past precipitation, has provided a wealth of ice-core isotopic records. Deuterium and ^{18}O measurements allow us (1) to reconstruct past temperature changes, (2) to access to past accumulation changes, related to water vapor pressure and thus to past surface temperatures, and (3) to derive information on conditions prevailing in the oceanic regions providing precipitation to Antarctica. The latter approach is based on the deuterium-excess parameter, $d = \delta\text{D} - 8\delta^{18}\text{O}$, which is influenced by the temperature of oceanic moisture sources and to a lesser degree by its relative humidity and prevailing wind speed.

In this article, we first examine the spatial distribution of water isotopes in Antarctica for present-day precipitation and assess the use of these observations (the present-day spatial slope) to derive temperature records back in time at a given site (the temporal slope). We then discuss paleoclimatic reconstructions based on this isotopic paleothermometer. Water isotope records are now available from a variety of Antarctic ice cores (Figure 1) both for the current interglacial period, the Holocene, and at the glacial–interglacial timescale with the longest record covering eight climatic cycles back to 800 ka BP.

Modern Precipitation Isotopic Composition and the Isotopic Paleothermometer

Surface snow sampled along traverse routes from coastal stations to inland sites can be analyzed for its isotopic composition (Masson-Delmotte et al., 2008). The linear relationship observed with temperature (Figure 2) can be modeled using a simple isotopic model as well as by isotopic general circulation models (GCMs) (atmospheric general circulation models

equipped with the explicit modeling of water isotopes). This well-explained ‘spatial slope’ is the basis for the use of stable isotope profiles measured along deep ice cores for temperature estimates (isotopic paleothermometry).

In order to assess the persistence of this spatial relationship in time (temporal slope), several studies have explored sites where long meteorological records are available together with isotopic records. Law Dome, a coastal site with particularly high accumulation rates (70 cm of ice equivalent per year at the Dome Summit South (DSS) ice-core site), offers the possibility of comparing the spatial slope, the seasonal slope (Delmotte et al., 2000; van Ommen and Morgan, 1997), and the decadal slope (Masson-Delmotte et al., 2003). At Vostok, due to the low accumulation rate (2.3 cm of ice equivalent per year) postdepositional effects such as wind scouring only permit to evaluate decadal slopes (Ekaykin et al., 2004).

Spatial or seasonal relationships between the site temperature and the isotopic content of the snow must however be regarded with caution. As reflected by the spatial fluctuations of the deuterium excess (Figure 2), they integrate the effect of both local condensation temperature and changes in moisture origin and distillation history. Isotopic modeling allows us to disentangle the relative impact of changes in evaporation conditions versus condensation conditions on isotopic distribution. Such an approach must be implemented for modern data (spatial variations, seasonal cycle with simple models; inter-annual to decadal variability with isotopic GCMs). In particular, simple isotopic models require an adjustment of the parametrizations controlling the type of distillation (closed vs. open cloud) or the dependency of supersaturation over ice crystals with respect to temperature. The latter parameter is also tuned in isotopic GCMs (Jouzel et al., 1991). For instance, at the Dome C site, we obtain the following relationships from linear regressions conducted on multiple simulations based on a simple isotopic model forced with varying evaporation and condensation conditions (in the range of glacial to interglacial changes):

$$\Delta\delta\text{D} = 7.6\Delta T_s - 3.6\Delta T_o \quad [1]$$

$$\Delta d = -0.5\Delta T_s - 1.3\Delta T_o \quad [2]$$

where T_s is the site temperature, T_o is the ocean surface temperature, and $\delta^{18}\text{O}_{\text{sw}}$ is the ocean water isotopic composition; the symbol Δ is used for anomalies between two time periods (Masson-Delmotte et al., 2004). From this modeling approach, one can in principle access both the site and source temperatures, once both δD and $\delta^{18}\text{O}$ are measured, as is now systematically done on Antarctic ice cores.

The local temperature record inferred from this set of equations, $\Delta T_s = 0.161 \times \Delta\delta\text{D} + 0.446 \times \Delta d$, is indeed very close (i.e., within $\pm 10\%$) to the one calculated using the present-day spatial slope as illustrated (Stenni et al., 2003) from the

Figure 1 Map showing the location of deep Antarctic ice cores.

temperature record reconstructed at the Dome C site from coisotopic δD and $\delta^{18}O$ determinations (Figure 2).

The validity of this simple model approach, in which the spatial slope is used as a surrogate of the temporal slope to estimate the surface temperature at the site, has been independently confirmed from isotopic GCMs. Comparison of simulations performed for glacial and present-day climates confirms that the temporal slope is close to the modern spatial isotope-temperature slope of inland Antarctica (Delaygue et al., 2000), (Werner et al., 2001). Unlike for Greenland, which is characterized by drastic glacial-interglacial changes in precipitation seasonality, Antarctic water-stable isotopes appear to provide reliable quantitative information on past temperature changes (within e.g., $\pm 20\%$), at least at the glacial-interglacial scale (Figure 3). Further confirmation of the validity of the isotopic paleothermometer comes from chronological constraints or from estimates of the gas age-Ice Age difference (Jouzel et al., 2003), (Blunier et al., 2004).

Holocene Isotopic Records

Last 200 Years

High-resolution isotopic measurements conducted on ice cores from high accumulation coastal sites have been used to reconstruct accumulation and temperature fluctuations during recent decades. In inland locations, deposition and postdeposition effects prevent such decadal-scale analyses unless numerous pits are stacked to provide a record of precipitation isotopic composition. Such an effort has been undertaken for Vostok (Ekaykin et al., 2004). At Vostok, δD multidecadal fluctuations appear to occur during the past two centuries, consistent with accumulation changes and Pacific decadal oscillation changes; these fluctuations, when translated into temperature changes, appear to remain within $1^\circ C$ of modern parameters. A small

increasing trend is detected over the past two centuries. In contrast to this, a high accumulation site such as Law Dome can provide an isotopic record with a subannual resolution (Morgan and Van Ommen, 1997; Schneider et al., 2006). Combined measurements of δD and $\delta^{18}O$ at Law Dome (Masson-Delmotte et al., 2003) revealed both that coastal Antarctic water-stable isotopes do capture multidecadal changes in temperatures (a local temperature increase since the 1960s) and that abrupt reorganizations in the advection of moisture toward Law Dome took place both in the 1940s and the 1970s, identified as 'steps' in Law Dome deuterium excess.

The diversity of locations where shallow ice cores have been extracted and analyzed for isotopic changes should enable the synthesis of the evolution of Antarctic snow isotopic composition over the past centuries with a decadal resolution. However, it must be stressed that coastal and inland snowfalls do not undergo similar distillation histories, and do not have similar moisture sources, as reflected by changes in deuterium excess. Systematic comparisons of decadal-scale deuterium excess fluctuations over the last centuries should bring new insights into the recent dynamics of water cycle and climate change. These aspects are also important for determining the mass balance of the ice sheet.

The Last Millennium

A comparison of isotopic records spanning this time period has been recently presented by Goose et al. (2004), who constructed a stack of East Antarctic deuterium records from South Pole, Taylor Dome, Talos Dome, EPICA Dome C, and Law Dome. This stack suggests that there is an apparent phase lag between the so-called Medieval warm period reconstructed in the Northern Hemisphere and the Antarctic warmest period that occurred one to two centuries later. Temperature fluctuations, reconstructed using the spatial slope, remained within $1^\circ C$ of modern parameters. This preliminary synthesis is limited by the availability of records (here only in a portion of east Antarctica), the lack of a common timescale, and the limited deuterium excess information.

Holocene

For the current interglacial period, a synthesis of 11 ice-core isotopic records has been achieved for δD (Masson et al., 2000). Although limited by the lack of a common age scale (based, for instance, on volcanic eruptions), this comparison revealed a consistent long-term isotopic pattern for Eastern Antarctica, with an early Holocene optimum of $5\text{--}10\text{‰}$ occurring $12\text{--}8$ ka BP. Following this optimum, different sites undergo different isotopic trends, possibly partly associated with the evolution of the ice-core site elevation; most of the sites exhibit a small decreasing trend. Superimposed on these long-term trends, the various ice cores reveal an organized millennial-scale periodicity associated with eight well-marked warm peaks and three well-marked cold peaks, the last one taking place during the last millennium. Spectral analyses conducted on all the records show several common intervals of significant periodicities in the multidecadal to centennial modes (from 70 to 240 yr periodicities). Unfortunately, the meteorological

Figure 2 Spatial variability of water-stable isotopes of modern Antarctic snow along traverse routes from Dumont d'Urville to Dome C (square points), interpolation (solid line) and comparison with distillation histories calculated by a cloud isotopic model in response to varying initial conditions (dashed lines). Adapted from Masson-Delmotte V, et al. (2004) Common millennial scale variability of Antarctic and southern ocean temperatures during the past 5000 years reconstructed from EPICA Dome C ice core. *The Holocene* 14: 145–151.

records in Antarctica are too short to independently verify presence of such long-term oscillations.

The Holocene deuterium excess fluctuations recorded on four of these records (Vostok, Dome B, Dome C, and Taylor Dome) were compared by Vimeux et al. (2001a). The common warming in the first half of the Holocene is attributed to a progressive warming of the oceanic moisture sources. Available paleoceanographic records reflect a progressive warming of the tropics together with a progressive cooling of the high latitudes. Holocene changes in obliquity, redistributing annual mean insolation changes at low versus high latitudes, could account for the observed deuterium excess increase, attributed to an increasing contribution of low latitudes to Antarctic precipitation during the Holocene. Again, although the long-term trends are common to all Antarctic records, millennial and high-frequency variability of the deuterium excess profiles

appear to be related to local processes and are not common to all the sites.

On EPICA Dome C, $\delta^{18}O$ and δD analyses conducted at a ~ 20 -yr resolution (Masson-Delmotte et al., 2004) were combined to quantify the compatible changes in moisture source and site temperatures. This approach suggests that the early Holocene optimum appeared first in Antarctic temperatures, followed 800 yr later by an optimum in the moisture source, and revealed a specific out-of-phase behavior relating site and source temperature occurring about 8 ka, similar to the situation taking place during the Antarctic cold reversal (see 'Antarctic Isotopic Records Over Glacial-Interglacial Cycles'). The reconstructed site and source temperature strongly covary at the centennial scale during the last 5 ka, suggesting the setup of a coupling mechanism between ocean moisture source and Antarctic temperature, possibly related to the onset of modern

Figure 3 Stable isotope records from deep Antarctic ice cores: Vostok, Dome F, Dome C.

El Niño southern oscillation (ENSO). Finally, this approach allows us to estimate that the peak warmth at the beginning of the Holocene was $\sim 1.5^\circ\text{C}$ warmer than today.

Antarctic Isotopic Records over Glacial–Interglacial Cycles

The Byrd ice core, drilled in West Antarctica ($80^\circ 01' \text{S}$, $119^\circ 31' \text{W}$), provided a record of precipitation $\delta^{18}\text{O}$ spanning almost one glacial climatic cycle ($\sim 80 \text{ ka}$) (Johnsen et al., 1972). Several other ice cores now cover the last deglaciation, on the western (Siple Dome) (Brook et al., 2005) and eastern (Taylor Dome) (Steig et al., 1998) sides of the Ross Sea, on the East Antarctic coast in the Indian Ocean sector (Law Dome) (Morgan et al., 2002), on the East Antarctic plateau (Komsomolskaia, Vostok, Dome B, Dome F, EPICA Dome C) (Lorius et al., 1979; Jouzel et al., 2001; Petit et al., 1999; Watanabe et al., 2003) and on the coast of the Atlantic sector of East Antarctica (EPICA Kohnen Station) (Figure 1). Moreover, three of these deep Antarctic ice cores cover more than one climatic cycle: Dome F spans three climatic cycles (Watanabe et al., 2003), Vostok four climatic cycles (Petit et al., 1999) and EPICA Dome C eight climatic cycles (EPICA-community-members, 2004).

Glacial–Interglacial Temperature Change

All inland east Antarctic deep ice cores show a consistency in their glacial to interglacial isotopic fluctuations with a typical amplitude of δD changes of $\sim 50\text{‰}$. The use of the spatial isotope-temperature slope to estimate the associated temperature range first requires a correction for the imprint of changes in ocean water isotopic composition associated with the buildup of glacial land ice masses. The impact of ocean surface isotopic composition, $\delta^{18}\text{O}_{\text{sw}}$, on Antarctic precipitation isotopic composition can be calculated explicitly, by correcting $\delta^{18}\text{O}$ from the factor $\delta^{18}\text{O}_{\text{sw}} \times (1 + \delta^{18}\text{O}) / (1 + \Delta\delta^{18}\text{O}_{\text{sw}})$

and similarly by correcting δD from the factor $8 \times \delta^{18}\text{O}_{\text{sw}} \times (1 + \delta^{18}\text{O}) / (1 + 8 \times \Delta\delta^{18}\text{O}_{\text{sw}})$ (Jouzel et al., 2003). The application of the spatial isotope temperature to inland Antarctic sites such as Dome C suggests a glacial to Holocene surface temperature change of $8\text{--}9^\circ\text{C}$ (Figure 4).

However, the change between glacial and modern conditions also involves profound reorganizations of the water cycle, from evaporation conditions to deposition conditions in interior Antarctica. Available deuterium excess records from inland sites (Jouzel et al., 1982; Stenni et al., 2003; Vimeux et al., 2001b; Watanabe et al., 2003) consistently show a 3‰ smaller deuterium excess at the Last Glacial Maximum (LGM). Taken together, the deuterium excess and δD constraints can be quantified in terms of changes in both source and site temperatures. In this case, the LGM–present-day estimated temperature change is only marginally affected ($\sim 0.5^\circ\text{C}$). Of course, many factors other than just surface temperature or source temperature can alter the isotope-temperature relationships, such as the factors controlling evaporation kinetics (relative humidity, wind speed), changes in cloud microphysics when atmospheric dust levels vary, changes in moisture advection history, changes in condensation versus surface temperature, or changes in the seasonality or intermittency of snow deposition.

Millennial Climate Variability in Antarctica

The water-stable isotope profiles from Antarctic ice cores do not undergo as rapid a variability during the Ice Ages as that recorded in Greenland, where this rapid variability reaches two-thirds of the full glacial–interglacial isotopic amplitude (Section Greenland). However, superimposed on the glacial–interglacial cycles, central Antarctic ice cores exhibit a succession of higher-frequency fluctuations reflected in many parameters analyzed in ice cores, including stable isotopes.

The last deglaciation as reflected in Antarctic water-stable isotopes does not appear as a continuous process but was interrupted by the so-called ‘Antarctic cold reversal’ (Jouzel et al., 1995) from about 14 to 13 ka BP. This cold reversal,

Figure 4 (a) Dome C water-stable isotope records (black, δD on the left axis; red, deuterium excess on the right axis) and (b) reconstructed temperatures during the past 45 ka (black, site temperature from the use of the spatial slope after correction for sea water isotopic composition; green, site temperature after inversion taking into account deuterium excess and sea water isotopic composition; red, source temperature after inversion taking into account deuterium excess and sea water isotopic composition). Adapted from Stenni *B. et al.* (2003) A high resolution site and source Late Glacial temperature record derived from the EPICA Dome C isotope records (East Antarctica). *EPSL* 217: 183–195.

identified in all Antarctic ice cores, could be the Antarctic counterpart of the abrupt warming corresponding to the Bölling-Alleröd recorded in Greenland ice cores, owing to the synchronization of bipolar ice cores using the atmospheric composition changes recorded in air from ice cores (Blunier *et al.*, 1997) (Morgan *et al.*, 2002) (Pedro *et al.*, 2011).

The last Ice Age is punctuated by a series of deuterium events, occurring at a pace of ~4–10 ka and with typical amplitudes of one-fourth to one-half of the full glacial-interglacial amplitude, with progressive increases and decreases over several millenia (Blunier and Brook, 2001; EPICA-community-members, 2006). These so-called ‘A’ events (labeled A1–A7 on Byrd ice core) (Blunier and Brook, 2001) have been placed on a common chronological framework with Greenland rapid events, using a synchronization based on methane rapid fluctuations. It appears that Antarctic temperatures increase progressively when Greenland is in a cold or cooling phase, reach their peak warmth when Greenland undergoes an abrupt warming associated with a Dansgaard-Oeschger event,

and then progressively decrease. This behavior appears to be related to a seesaw mechanism involving reorganizations of the ocean circulation and heat transport, particularly marked during the largest Dansgaard-Oeschger events.

High-resolution deuterium and deuterium excess measurements conducted on EPICA Dome C ice core and spanning the last 45 ka have allowed us to propose a quantitative reconstruction of these rapid events; at the resolution achieved here, all Greenland rapid events appear to have Antarctic counterparts (Stenni *et al.*, 2003). Taking into account deuterium excess fluctuations reveals that rapid deuterium fluctuations (ACR, A1 event, millennial-scale fluctuations of smaller amplitude) cannot be explained by changes in source conditions, and correspond to Antarctic temperature fluctuations of ~1 to ~2 °C. During the past 45 ka, a strong correlation is observed between the reconstructed site to source temperature gradient and the aerosol fluxes derived from chemical analyses of the ice core, revealing a strong link between meridional temperature gradients and atmospheric transport of aerosols to Antarctica.

For the most rapid deuterium fluctuation recorded in Vostok ice, the 5d/5c transition that took place ~ 107 ka BP (GT4 age scale), [Caillon et al. \(2001\)](#) applied the gas-fractionation method recently developed as an alternative paleothermometry method for Greenland rapid events. This method enables the precise assessment of the phase lag between the Antarctic temperature increase (as seen in deuterium and $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ of the air trapped in the ice) and Northern Hemisphere temperatures (as recorded in Vostok methane concentration). The temperature signal inferred from $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ is attributed to changes in a gravitational fractionation resulting from changes in firn thickness and close-off depths. This change in close-off depths enables the assessment of changes in temperatures. This method confirms again that, for central Antarctica (here Vostok), the classical use of water-stable isotopes remains valid within 20%, not only for glacial–interglacial changes but also during rapid events.

Finally, the first rapid events of the last Ice Age have recently been analyzed from a bipolar perspective owing to a preliminary synchronization of NorthGRIP ice core (Greenland) and Vostok ice. This common age scale was constructed based on the 5d/5c transition identified in methane from both poles and also on the air $\delta^{18}\text{O}$ from both sites ([Landais et al., 2005](#)). It appears that the onset of the last Ice Age began by a common bipolar cooling that lasted at least 5 ka. In Greenland, this progressive cooling was interrupted by a first Dansgaard–Oeschger event (D/O 25), which does not have a clear Antarctic counterpart as seen in the Vostok deuterium profile. However, the following D/O events 24 and 23 are clearly associated with Antarctic counterparts, similar to the rapid events occurring during full glacial conditions.

Glacial–Interglacial Cycles

Three deep Antarctic ice cores span several climatic cycles: Dome F (three climatic cycles) ([Watanabe et al., 2003](#)), Vostok (four climatic cycles) ([Petit et al., 1999](#)), and Dome C (eight climatic cycles) ([EPICA-community-members, 2004](#)). Over the overlap period, the deuterium records of these three sites exhibit very similar fluctuations, confirming both the spatial representativity of stable isotope records from inland East Antarctica. A comparison of ice-core deuterium records with marine global ice volume records ([Liesicki and Raymo, 2005](#)) shows also a large similarity ([EPICA-community-members, 2004](#)), revealing the imprint of 100 ka cycles and periodicities associated with obliquity and precession ([Petit et al., 1999](#)). Glacial maximum levels appear rather stable over time, although Antarctic ice-core deuterium fluctuations depict a variety of warm periods. A classical use of the spatial isotope-temperature relationship suggests that temperatures up to $\sim 5^\circ\text{C}$ above present-day levels occurred during marine isotopic stages 5 and 9 ([Watanabe et al., 2003](#)).

The longest interglacial period occurred about 400 ka, and corresponding with marine isotopic stage 11. As expected from considerations of thresholds in 65°N mid-June insolation resulting from the low eccentricity ([Berger and Loutre, 2002](#)), this interglacial period lasted ~ 28 ka in the first Dome C age scale. Its peak warmth corresponds to a temperature $\sim 2.5^\circ\text{C}$ above present-day level, using the spatial isotope-temperature relationship.

Deuterium excess measurements have been conducted on Vostok and Dome F ice cores over several climatic cycles ([Watanabe et al., 2003](#); [Vimeux et al., 1999](#); [Vimeux, 2001b](#)). These measurements have revealed the stability of evaporation conditions during glacial–interglacial cycles; reconstructed source temperature fluctuations remain within $\sim 3^\circ\text{C}$ of modern parameters. The impact of changes in source conditions remains generally limited in deuterium fluctuations, apart from glacial inception. During glacial inceptions, deuterium excess levels remained high when deuterium levels decreased. Over the past 250 ka, the Vostok and Dome F deuterium-excess profiles were strongly influenced by changes in the obliquity of the Earth's orbit. It is suggested that small obliquities induce warmer tropics, colder high latitudes, larger low to high latitude gradients, and a more intense transport of moisture from warm low latitude areas to the poles. All these effects combine to generate a high deuterium excess during periods of small obliquities, and a systematic antiphase behavior between deuterium excess of Antarctic ice and obliquity. The marked high levels of deuterium excess at the onset of Ice Ages result from this general link with obliquity and point to large reorganizations of the water cycle during glacial inceptions, providing the moisture required in the high Northern Hemisphere latitudes to build up large ice caps ([Vimeux et al., 1999](#)) ([Vimeux, 2001b](#)).

Conclusions and Perspectives

When ice cores are drilled in Antarctica, water-stable isotope records are now among the essential analyses to quantify past changes in climate and hydrological cycle, and to date the ice cores. The state-of-the-art of the paleothermometry method and climate modeling suggest that on both glacial–interglacial and rapid event timescales they provide reliable and quantitative indications of past climate change ([Figure 5](#)). Further progress on the quantification of uncertainty sources such as changes in evaporation conditions may arise from $\delta^{17}\text{O}$ analyses of Antarctic snow and ice, and the combination of isotopic modeling and analyses of atmospheric back-trajectories, together with an improved characterization of the modern spatial distribution in unexplored regions of Antarctica. Obtaining more information on past climate changes from water-stable isotopes in Antarctic ice cores requires analyses at the highest possible temporal resolution, together with the collection of new ice cores both at high accumulation sites (to reconstruct climate change during the last millennia) and very low accumulation sites (to extend the records before 1 Myr). Deep ice cores are now being planned at the international level within the International Partnership for Ice Core Science (IPICS) umbrella.

Greenland Stable Isotopes

The Early Isotope Work

By doing stable isotope investigations of frontal precipitation over Copenhagen, Denmark, in the early 1950s, Willi Dansgaard discovered a correlation between condensation temperatures and isotopic ratios. Subsequently, Dansgaard proposed in a groundbreaking paper that paleoclimate could be studied by doing stable isotope measurements on Greenland ice cores (Dansgaard, 1954). At this time, no ice cores were available from Greenland for such investigations, and the immense scientific scope of this proposal was hardly realized even 15 years later when the first results from the Camp Century core became available. Carl Benson of the US Army Snow, Ice, and Permafrost Research Establishment (SIPRE) was, however, already doing pit studies in Northwest and Central Greenland in the early and mid-1950s (Benson, 1962). In cooperation with Epstein and Sharp, he discovered the very strong annual isotopic cycle in the Greenland snow pack. Eventually, this cycle became most useful for measuring accumulation rates and dating ice cores. When the Site 2 ice core (see Figure 1), which was drilled by SIPRE in preparation for the International Geophysical Year's Antarctic activities in 1957, became available in 1955, Chester C Langway, also from SIPRE, initiated the modern era of multidisciplinary ice-core studies including detailed isotope profiles deep down in the core (Langway, 1967). The Site 2 isotope data (Epstein and Sharp, 1959) showed a clear annual cycle below the firn layers, but smoothed compared with the isotope data from Benson's pit studies (Langway, 1967). Thus, Langway discovered the effect of firn diffusion discussed below.

Willi Dansgaard continued his studies in Greenland and discovered the isotopic latitude effect for Greenland and the strong correlation between mean annual temperatures and isotopic values on the ice cap (Dansgaard, 1961). He also used the Rayleigh condensation model to improve the understanding of the physical basis for the climatic information contained in natural precipitation. Most of his earlier results are summarized in his classic Tellus paper (Dansgaard, 1964) where he also provided the first results from the International Atomic Energy Agency (IAEA) precipitation network and introduced the concept of deuterium excess.

The Camp Century deep ice core was recovered by Lyle Hansen and his coworkers from the US Army Cold Region Research and Engineering Laboratories in 1966. Two years later, Dansgaard suggested that Langway do a comprehensive isotope study on the core, a proposal that Langway accepted. This most fruitful cooperation was later extended with the group of Hans Oeschger from Bern, Switzerland, and became the basis for the Greenland Ice Sheet Program (GISP) that managed to recover a deep core from Dye-3 South Greenland with a new Danish deep drill in 1981. When the first Dye-3 isotopic results were published (Dansgaard et al., 1982), the immense impact of the isotopic paleostudies on Greenland

deep ice cores was firmly established. In the early 1970s, the Danish group also built a unique inlet system for running 512 daily mass-spectrometric oxygen-isotope measurements. The original aim was to date the Dye-3 core by counting annual isotopic cycles through most of the Holocene by measuring a total of 80 000 samples. However, this system greatly strengthened the isotope work done with subsequent Greenland ice cores and over one million samples were analyzed using it.

Shallow Ice Cores – The Role of Diffusion

A large number of ice cores reaching depths of 100–200 m have been drilled at various locations on the Greenland ice sheet. Such cores offer a time span ranging from a few centuries to thousands of years, depending on core depth and local accumulation rates. As instrumental climatic observations are limited to the past two centuries for most of the Northern Hemisphere, the records of $\delta^{18}\text{O}$ from shallow ice cores are a valuable asset when investigating relationships between climate and $\delta^{18}\text{O}$. Due to the multiple cores available, it is possible to stack the records and thereby reduce the glaciological noise in the $\delta^{18}\text{O}$ data. Using cores from various locations, it is also possible to resolve local climatic variations affecting only parts of the ice sheet. The investigation of $\delta^{18}\text{O}$ records from the upper part of the ice cores is complicated by water vapor diffusion in the pores of snow and firn in the top 60–70 m of the ice sheet. This diffusion tends to smooth the high-frequency oscillations of the $\delta^{18}\text{O}$. Figures 2 and 3 show the diffusion-related decay of the annual $\delta^{18}\text{O}$ cycle for a central Greenland shallow core.

The Climate Signal in Seasonal $\delta^{18}\text{O}$

The close relationship between $\delta^{18}\text{O}$ and site temperature makes $\delta^{18}\text{O}$ a valuable proxy both for Greenland climate and Northern Hemisphere atmospheric circulation patterns. To exploit the potential of Greenland $\delta^{18}\text{O}$ records fully Vinther et al. (2003, 2010) have shown that it is essential to consider seasonal oscillations in the $\delta^{18}\text{O}$ records.

In the vast areas of the Greenland ice sheet where annual accumulation exceeds 20 cm of ice equivalent, seasonal oscillations of $\delta^{18}\text{O}$ can be retrieved through most of the Holocene. In areas of lower accumulation, the seasonal $\delta^{18}\text{O}$ cycles are obliterated by the diffusion in the upper snow and firn layers.

As can be seen in Figures 2 and 3, the seasonal cycle of $\delta^{18}\text{O}$ is influenced by diffusion even in areas with accumulation rates larger than 20-cm ice equivalent per year. In the top 60–70 m of the ice sheet, a marked decay in amplitude of the $\delta^{18}\text{O}$ cycle can be observed. If a climatic interpretation of seasonal $\delta^{18}\text{O}$ values is to be pursued, it is necessary to

understand the diffusion process that masks the seasonal oscillations in the $\delta^{18}\text{O}$ signal.

Figure 1 Locations of selected Greenland ice cores. The Site 2 core was the first ice core drilled in Greenland. The Camp Century, Dye-3, GISP2, GRIP, NGRIP, and Renland cores all contain ice from the Holocene, Glacial, and Eemian periods.

Figure 2 Measurements of $\delta^{18}\text{O}$ from different depths in the Site E central Greenland ice core. Left: near the surface before firn diffusion dampens the annual cycle. Right: below the diffusion zone, the annual cycle is significantly dampened. The thin curve is diffusion-corrected data. Annual accumulation at Site E amounts to 21 cm of ice equivalent.

In a publication by Johnsen (1977), the first step was taken in comprehending the physics behind the diffusion process. Later papers by Merlivat and Jouzel (1979), Herron and Langway (1980), and Schwander et al. (1988) led to the Johnsen et al. (2000) paper in which a physical model covering both $\delta^{18}\text{O}$ and δD diffusion was presented and validated. The Johnsen et al. (2000) model predictions of the diffusion-driven dampening of the annual $\delta^{18}\text{O}$ cycle can be seen in Figure 3.

Using the Johnsen et al. (2000) diffusion model and the mathematical formulation of the diffusion problem presented in Johnsen (1977), it is possible to correct $\delta^{18}\text{O}$ series for diffusion. An example of diffusion-corrected $\delta^{18}\text{O}$ data can be seen in Figure 2(b). Having diffusion-corrected data, the underlying seasonally resolved climatic signal can be retrieved from ice-core $\delta^{18}\text{O}$ records.

It is easy to demonstrate the importance of correcting the seasonal $\delta^{18}\text{O}$ records for diffusion before any climatic interpretation is pursued. Four different central Greenland ice cores were drilled in 1984/1985 about 500 km from the coastal Tasilaq meteorological station. Table 1 demonstrates that correlations between winter season $\delta^{18}\text{O}$ and December-to-March temperatures at the Tasilaq station (Laursen, 2003) are greatly improved by diffusion correcting the records. Furthermore, it can be seen that the ice-core records from the areas of modest accumulation (Sites E and G) benefit the most from the diffusion correction.

Using the approach of diffusion correction on several Greenland ice cores, Vinther et al. (2003, 2010) demonstrated that winter season $\delta^{18}\text{O}$ from Greenland ice cores contained both a distinct Greenland temperature signal and the signature of the North Atlantic Oscillation (NAO), a large-scale atmospheric flow pattern. In fact, Greenland annual average temperatures were found to be better captured by winter season $\delta^{18}\text{O}$ data than annual average $\delta^{18}\text{O}$ data.

A linear regression between the multi-ice core winter $\delta^{18}\text{O}$ signal and Northern Hemisphere December-to-March sea level pressure (slp) is seen in Figure 4. The NAO pattern with opposite pressure trends over Iceland and the Azores is clearly seen in Figure 4. The regression was carried out for the years

Figure 3 Amplitude of the annual $\delta^{18}\text{O}$ cycle in the Site E central Greenland ice core and model estimate.

Table 1 Correlations (r) of winter $\delta^{18}\text{O}$ with Tasiilaq December-to-March temperatures (1895–1982)

Ice core	Site A	Site B	Site E	Site G	Mean ABEG
Accumulation (ice equivalent; cm)	29	31	21	25	–
r (before diffusion correction)	0.29	0.43	0.25	0.21	0.36
r (after diffusion correction)	0.33	0.50	0.41	0.37	0.52

1872–1970 and the slp-data are from the HadSLP1 dataset (Basnett and Parker, 1997).

Deep Ice Cores – Climate During 125 Millennia

During the past 40 years a total of five deep ice cores have been drilled all the way through the Greenland ice sheet. All five records contain ice from the entire Holocene, the last glaciation, and the Eemian. A sixth ice core drilled through the small east coast Renland ice cap also reaches back into the Eemian (for drill site locations see Figure 1). Measurements of $\delta^{18}\text{O}$ have been carried out on the full length of all six ice-core records. From Figure 5 it is clear that the six $\delta^{18}\text{O}$ records are very similar for the past 40 000 years. Below 40 000 years, the Dye-3 record is disturbed by ice flow, as is the Renland core below 60 000 years. The Greenland Icecore Project (GRIP) and GISP2 records are affected by flow-induced foldings below 105 000 years. The North Greenland Icecore Project (NGRIP) core presents the only $\delta^{18}\text{O}$ record known to be stratigraphically continuous into the Eemian. However, Eemian ice is found in all six ice cores.

Timescales for Deep Ice Cores

A prerequisite for the climatic interpretation of the deep ice cores is having a well-established depth–age relation. For most

Figure 4 December–March slp-response to a one-sigma increase in winter $\delta^{18}\text{O}$ in a series based on multiple Greenland ice cores. Contour interval is 0.4 hPa, red contours are positive while blue are negative.

of the Holocene, counting annual layers using the seasonal oscillations in $\delta^{18}\text{O}$ is a very robust way of obtaining a time-scale for the Greenland ice cores. During the glacial, generally lower accumulation rates lead to diffusion-caused obliteration of the annual $\delta^{18}\text{O}$ cycles, rendering annual layer counting impossible.

The first approach to date the glacial part of the ice cores relied on analytical 2D flow model estimates of the progressive thinning of annual layers (Dansgaard and Johnsen, 1969). The flow model presented by Dansgaard and Johnsen (1969) (D–J model) proved to be very adaptive and Johnsen and Dansgaard (1992) refined the analytical D–J model to account for both increased shear near the bottom of the ice sheet and sliding of the ice sheet over the bedrock. The D–J model can also be modified to include flow due to bottom melting affecting the ice sheet.

To include temporal variations of the accumulation rate, a numerical version of the D–J model was required. The first effort to create such a model was made by Johnsen et al. (1992). Numerical D–J flow models have been used to provide timescales to both the GRIP and the NGRIP ice cores (NGRIP members, 2004). These models require past accumulation rates as an input parameter. This requirement can be fulfilled by using the relationships between $\delta^{18}\text{O}$ and accumulation rate at the drill sites. Figure 6 shows the Dye-3, GRIP, and NGRIP $\delta^{18}\text{O}$ profiles on timescales derived from numerical D–J flow models. As the bottom-most part of the Dye-3 core is disturbed by ice flow, only the past 40 000 years of the Dye-3 profile is shown. The similarity of the three profiles is striking.

The first effort to count annual layers during the glacial was carried out on the GISP2 core (Meese et al., 1997). Seasonally changing features in the visual stratigraphy of the GISP2 core were used for counting the layers. Surprisingly, the glacial GISP2 timescale derived from this methodology did not show a persistent relationship between the $\delta^{18}\text{O}$ and the

Figure 5 Early Holocene, Glacial, and Eemian $\delta^{18}\text{O}$ records from six Greenland ice cores are shown. The cores are all on depth scales. The NGRIP timescale is shown, and the numbers on the left side of the scale give the most prominent interstadials.

Figure 6 Profiles of $\delta^{18}\text{O}$ from the Dye-3, GRIP, and NGRIP cores, on the ss09sea flow-modeled timescale. Numbers are given for the most prominent interstadials. b2k, before AD 2000.

accumulation rate back in time. Such a relation is underpinned both by modern observations and the following simple argument: a change in $\delta^{18}\text{O}$ is associated with a change in site air temperature, and as the air temperature determines the maximum water vapor content of the air, the amount of moisture reaching the site will be related to observed $\delta^{18}\text{O}$ values.

Based on a new effort to date the glacial part of the NGRIP core using both seasonal oscillations in chemical impurities and visual stratigraphy, it is now believed that the apparent breakdown of the $\delta^{18}\text{O}$ /accumulation relationship observed in the GISP2 core is an artifact caused by erroneous

interpretation of the GISP2 visible strata (Andersen et al., 2006; Svensson et al., 2006).

The Holocene

The major part of the deep ice cores consists of Holocene ice. Looking at Figure 7, it is obvious that millennial scale trends in the ice core records are different during the course of the Holocene. Vinther et al. (2009) have shown that these differences are most likely due to a combination of past Greenland ice sheet elevation change and upstream effects (i.e., that ice in

Figure 7 Holocene profiles of $\delta^{18}\text{O}$ deviations with respect to present. Heavy lines show millennial scale trends in the data. All profiles are shown on the GICC05 time scale, except for GISP2 $\delta^{18}\text{O}$ which is shown on the original GISP2 time scale. b2k, before AD 2000.

the lower strata originates from higher elevation positions upstream from the drill site). Furthermore, [Vinther et al. \(2009\)](#) demonstrated, that the average $\delta^{18}\text{O}$ from the two small ice caps of Renland (eastern Greenland) and Agassiz (Ellesmere Island north west of Greenland) can be used to establish the Holocene climatic $\delta^{18}\text{O}$ evolution, if corrected for post-glacial rebound (the corrected average $\delta^{18}\text{O}$ is shown as the black curve in [Figure 7](#)).

The differences between the Renland/Agassiz $\delta^{18}\text{O}$ average and $\delta^{18}\text{O}$ from the other five ice cores shown in [Figure 7](#) can thus be converted directly to past changes in depositional elevation at the five locations using the observed $\delta^{18}\text{O}$ -elevation relationship for Greenland.

A conversion of the Renland/Agassiz $\delta^{18}\text{O}$ average to past Greenland temperatures show a climatic optimum 2–3 °C warmer than present ([Vinther et al., 2009](#)) in good agreement with results from [Dahl-Jensen et al. \(1998\)](#) showing that bore-hole temperature measurements at GRIP and Dye-3 imply that temperatures on the ice sheet were, 3 °C higher than present during the climatic optimum. All but one of the $\delta^{18}\text{O}$ records shown in [Figure 7](#) are plotted on the Greenland Ice Core Chronology 2005 (GICC05). GICC05 is a newly counted time-scale that synchronizes the ice cores using common volcanic reference horizons ([Rasmussen et al., 2006; Vinther et al., 2006, 2008](#)). Exploiting the synchronization of the $\delta^{18}\text{O}$ records ([Rasmussen et al., 2007](#)) showed that the only significant common events in the early Holocene Dye-3, GRIP, and NGRIP records are the decreases in $\delta^{18}\text{O}$ some 8200, 9300, and 11400 years ago.

These events are known as the 8.2 ka and 9.3 ka cold events and the Preboreal oscillation, and they are observed in ocean sediment cores, tree ring data, and stalagmite records from all over the Northern Hemisphere. The events are believed to be associated with very large freshwater outbursts from the decaying Laurentide ice sheet. The large amount of freshwaters would temporarily weaken the North Atlantic overturning

circulation thereby diminishing the oceanic heat transport towards the polar region.

The Last Glaciation

The abrupt shifts in $\delta^{18}\text{O}$ leading to the warm Greenland interstadials ([Dansgaard et al., 1993; Johnsen et al., 1992](#)) are often referred to as Dansgaard–Oeschger events. These events are the most prominent features observed in the glacial parts of all Greenland ice cores (see [Figures 5](#) and [6](#)). The shifts are most probably due to large-scale reorganizations of the atmospheric and oceanic circulations during the glacial. Hence, full glacial (stadial) conditions are probably related to a shutdown of the North Atlantic overturning circulation, while the interstadials are warmed by the return of the overturning circulation. Changes from stadial climatic conditions to the 10–15 °C warmer interstadial climate are believed to have happened within a decade or two. The glacial climate is therefore characterized by a degree of instability that cannot be found during the Holocene. This instability is likely to be caused by the N–S shifts of the atmospheric polar front that follows the oceanic polar front ([Ruddiman and McIntyre, 1981](#)) in the glacial. The $\delta^{18}\text{O}$ at the polar front is close to –8‰ [Dansgaard and Tauber \(1969\)](#), which is also likely valid in the glacial. The Greenland $\delta^{18}\text{O}$ values are mainly driven by the latitudinal gradient of –0.54‰ $\delta^{18}\text{O}/\text{lat}$, the distance to the polar front and elevation changes [Dansgaard \(1961\)](#) and [Johnsen et al. \(1989\)](#).

[Johnsen et al. \(1997\)](#) estimated the $\delta^{18}\text{O}$ short-term annual RMS (Root Mean Square) variability from the GRIP ice core ([Figure 5](#) in that paper). The records of annual variability ([Figure 5\(c\)](#)) and the $\delta^{18}\text{O}$ ([Figure 5\(a\)](#)) are in anticorrelation. The RMS variability for Holocene, interstadials, and stadials are 0.9‰, 1.8‰, and 3.4‰, respectively. The increased variability is partly due to lower accumulation rate, in the interstadials and stadials, and partly due to the rapid N–S shifts of the polar front during these cold periods.

Table 2 Average values and differences of $\delta^{18}\text{O}$ during different climatic periods (all values are given in ‰)

Drill site	Present (P)	Stadial (S)	Eemian (E)	P–S	E–P
Camp century	–29.5	–41.9	–27.0	12.4	2.5
Dye-3	–27.6	–36.1	–22.9	8.5	4.7
GISP2	–35.0	–42.2	–32.3	7.2	2.7
GRIP	–35.1	–411.9	–31.6	6.6	3.5
NGRIP	–35.4	–44.5	–32.3	9.1	3.1
Renland	–27.3	–32.1	–23.8	5.0	3.5

Johnsen et al. (1992) found that an intercomparison between glacial $\delta^{18}\text{O}$ values observed in different Greenland ice cores shows important differences in the size of the $\delta^{18}\text{O}$ increase associated with the shift from stadial to Holocene climatic conditions. The Camp Century core shows the largest $\delta^{18}\text{O}$ changes while the changes at Renland are the most modest (see Table 2 and Figure 5). It is most likely that the large changes in Camp Century (and NGRIP) $\delta^{18}\text{O}$ are related to elevation changes, but the changes could also be partly due to a strongly depleted northwesterly source of precipitation during the stadials at those sites. Such a source would stem from a split in the polar jet-stream, with branches both north and south of the Laurentide ice sheet. Precipitation arriving from the north-west would not be able to reach the Renland ice cap as it is situated east of the main ice sheet, and therefore, is shielded from any such precipitation. Hence, the relatively modest decrease in Renland $\delta^{18}\text{O}$ values during the stadials can be understood in terms of the Renland ice cap not receiving precipitation from the depleted northern branch of a split jet-stream.

Recent atmospheric modeling efforts suggesting a split jet-stream during the glacial in the winter (i.e., Bromwich et al., 2004) therefore enjoy significant support from observations of stadial $\delta^{18}\text{O}$ in Greenland ice cores. The whole glacial period in Camp Century is $\sim 3\text{‰}$ colder compared to the present than seen in NGRIP. This difference is most likely caused by $\sim 500\text{--}600$ m higher elevation at the Camp Century compared to the NGRIP elevation.

The Eemian

Ice from the last interglacial, the Eemian, has been found near the bedrock in all deep ice cores retrieved from the Greenland ice sheet (see Figure 5). It is, therefore, safe to conclude that most of Greenland was covered by ice during the Eemian. By using the $\delta^{18}\text{O}$ values observed in Eemian ice, it is possible to further quantify the changes in the size of the Greenland ice sheet during the Eemian.

Comparing present day $\delta^{18}\text{O}$ values to those observed in the Eemian ice, it is clear that the Eemian had 2.5–3.5‰ higher $\delta^{18}\text{O}$ values than presently observed all across Greenland (Table 2 and Figure 5) except for at the southern Dye-3 site. At Dye-3, Eemian $\delta^{18}\text{O}$ was 4.7‰ higher than recent values. The observed $\delta^{18}\text{O}$ value at a site on the Greenland ice sheet is dependent on elevation (the gradient is approximately -0.6‰ per 100 m altitude according to Johnsen et al., 1989). It can therefore be inferred from the rather uniform ($\sim 3\text{‰}$) increase

in Eemian $\delta^{18}\text{O}$, that the differences in elevation between the Camp Century, GRIP, GISP2, NGRIP, and Renland sites during the Eemian were almost equal to those presently observed. Furthermore, the elevated Eemian $\delta^{18}\text{O}$ values at the Dye-3 site indicate that the southern part of the Greenland ice sheet was lowered by some 400 m relative to the rest of the ice sheet (the 1.5‰ extra change at Dye-3 added to a 1‰ change due to ice flow induced extra lowering of the Eemian $\delta^{18}\text{O}$). It is more difficult to access the absolute elevation of the main ice sheet during the Eemian. The general $\sim 3\text{‰}$ increase in $\delta^{18}\text{O}$ could be attributed both to changes in elevation and changes in temperature, as the Greenland climate during the Eemian was significantly warmer than the present climate.

The fact that the small Renland ice cap experienced almost the same increase in $\delta^{18}\text{O}$ as most of the Greenland ice sheet does however put constraints on the possible changes in elevation. The Renland ice cap is only about 330 m thick, and due to its position on a high elevation plateau, it cannot grow any thicker. Furthermore, the fact that a more than 3-m-thick layer of Eemian ice has been found close to bedrock at Renland (see Figure 5) does suggest that the Renland ice cap was well preserved during the Eemian. The ice flow-driven thinning rate in the Renland ice cap estimated by Johnsen and Dansgaard (1992), probably could not have allowed the preservation of a 3-m thick slab of Eemian ice, had the Renland ice cap been significantly thinner during the Eemian than today.

It is, therefore, reasonable to assume that the Eemian thickness of the Renland ice cap was not very far from the 330 m observed today, thus imposing narrow constraints on thickness changes at Camp Century, GISP2, GRIP, and NGRIP as well. Given this information, it is obvious that most (if not all) of the 2.5–3.5‰ Eemian increase in $\delta^{18}\text{O}$ should be attributed to temperature change; not to elevation change. Hence, it is probably only the southern part of the Greenland ice sheet that experienced significant decreases in thickness during the Eemian. In fact it could be argued that a slight increase in the thickness of the northern part of the Greenland ice sheet is supported by the $\delta^{18}\text{O}$ data, as NGRIP and Camp Century Eemian $\delta^{18}\text{O}$ seems to have increased a bit less than the Renland $\delta^{18}\text{O}$.

Introduction

Stable isotope records from ice cores in Greenland reveal a repeated pattern of abrupt warmings and coolings during the last Ice Age ([Figure 1](#)). These cycles are widely known as 'Dansgaard-Oeschger' (D-O) oscillations, named after two pioneers in the study of ice core climate records. While these abrupt changes were known from earlier data, the publication of high-quality long records from the Greenland Ice Sheet Project 2 (GISP2) and Greenland Ice Core Project (GRIP) ice cores in the early 1990s made their significance clear, and spawned large-scale efforts to document such changes elsewhere, and understand their underlying cause.

The warm/cool D-O cycles are characterized by abrupt (taking place over decades; [Alley et al., 1993](#)) and large ($>10^{\circ}\text{C}$; [Severinghaus and Brook, 1999](#)) warming, generally followed by one to several thousand years of declining temperatures, and finally abrupt cooling ([Figure 1](#)). Temperature reconstructions based on the stable isotope records are bolstered by other techniques that verify the very large temperature shifts associated with the D-O events ([Cuffey et al., 1995](#); [Severinghaus and Brook, 1999](#)).

One way to gain insight into the dynamics of the D-O events is to understand their manifestation in other parts of the globe. Doing so requires obtaining climate proxy data with time resolution appropriate for examining climate variations on time scales of at least centuries, and preferably shorter, to approach the detail provided by the ice core records. Although such records are not abundant, they do exist. Accurate dating is equally important. Comparison of ice cores with marine terrestrial sediment records can be difficult because different dating methods are used, with varying accuracy and precision, making it difficult to be sure of the temporal phasing of events in different records. Some paleoclimate archives can be dated quite accurately, for example, corals or speleothems with U-Th dating, or varved ice and sedimentary deposits, but such records are relatively rare and not always continuous.

However, because the relative timing between records is often of most interest, another set of techniques can be used. Establishing relative chronologies only requires that demonstrably synchronous stratigraphic markers be available. Oxygen isotope records from Foraminifera shells in marine sediments have been used for this purpose for some time although precision is limited by the relatively slow pace of change of the isotope signal, and the influence of local temperature on the isotopic composition of the shells. More recently, records of atmospheric gases provide a similar tool for ice cores. This article reviews correlations of polar ice core records and the results of comparing records from the Northern and Southern Hemispheres on common chronologies, primarily using gas records.

Techniques

Correlation techniques discussed here rely primarily on records of relatively long-lived atmospheric gases that have globally synchronous variations. Gases with lifetimes longer than the mixing time of the atmosphere become homogenized, and substantial changes in sources or sinks result in synchronous concentration variations. Gases used as stratigraphic markers must also exhibit variations on time scales useful for chronology – constant or very slowly varying concentrations would be of limited use. The isotopic composition of atmospheric oxygen ($\delta^{18}\text{O}_{\text{atm}}$) and the concentration of atmospheric methane ([Bender et al., 1994](#); [Blunier and Brook, 2001](#); [EPICA Community Members et al., 2006](#)) both fulfill these criteria. Many other gases might be used for additional chronological constraints but have not yet been applied in this context.

Creating a stratigraphic framework using gas records involves several steps. The starting point is an accepted chronology for one core; in most recent work the GISP2, GRIP, or North GRIP (NGRIP) records from Greenland are used. New results from the NEEM ice core in northwest Greenland will add to this data set in the next few years. These Greenland chronologies provide an age versus depth curve for the ice, with the most accurate age scales based on counting annual layers. Trapped gases are younger than the surrounding ice due to the fact that air diffuses through the firn layer (snowpack) of polar ice sheets and is trapped at depth. Glaciological models are used to account for this difference (called delta age), allowing calculation of a gas age versus depth curve. These models require estimates of temperature and snow accumulation rate; these are typically derived from proxies like stable isotopes, layer thickness measurements, ^{10}Be concentrations, and other glaciological data. Correlation or 'curve matching' of this reference gas record is then made with the analogous record in a core from another location, providing a gas age versus depth curve. This has been done by manually picking control points for correlation, or by various numerical algorithms. To obtain a chronology for parameters measured in the ice phase of this second core a delta age calculation must again be applied to translate the new curve of gas age versus depth to Ice Age versus depth.

The steps taken depend on the specific problem at hand. In some cases, a gas chronology forms the primary basis for an ice core chronology, as is the case for dating the Vostok ice core through correlations of atmospheric oxygen isotopes with the marine isotope record ([Sowers et al., 1993](#)) and subsequent dating of the 50–110,000 year section of the GISP2 core by tying it to Vostok ([Bender et al., 1994](#)). Dating Antarctic ice cores through correlation with Greenland has used the Greenland ice chronologies as a starting point ([Blunier and Brook, 2001](#); [Blunier et al., 1998](#); [Brook et al., 2005](#); [EPICA Community Members et al., 2006](#); [Steig et al., 1998](#)).

Figure 1 The water–oxygen isotope record from the GISP2 ice core (Grootes et al., 1993). The isotope ratio is expressed as per mil deviation from a standard and is a temperature proxy. Higher values indicate warmer temperatures.

Figure 2 Records of atmospheric methane and $\delta^{18}\text{O}_{\text{atm}}$ from the GISP2 (Greenland), GRIP, Byrd (Antarctica), and Vostok (Antarctica) ice cores. The figure shows how variations in globally distributed gas signals can be matched between the hemispheres. Methane data from Brook et al. (1996), Brook et al. (2000), Blunier and Brook (2001), and Chappellaz et al. (1993); oxygen isotope data from Bender et al. (1999).

Each step in the process of translating a chronology from one core to another involves linked uncertainties, which must be incorporated in the final uncertainty estimate for the new chronology. The first is that of the absolute age scale for the ice record used as the primary chronology. This uncertainty is not relevant if only relative chronology between cores is of interest. Additional relevant uncertainties include uncertainty in delta age models and correlation uncertainties related to sample resolution and variability in the original signal – periods of higher variability create a greater number of targets for matching records. The importance of the various uncertainties depends on the nature of the ice core records and the gas parameter used for correlation. Delta age is relatively small and well constrained for warm, high accumulation rate sites

like central Greenland today (where delta age is ~ 200 years), but at cold low accumulation sites like Vostok or Dome C in east Antarctica, Delta age is slightly greater than 3000 years today and may have reached 6000–8000 years during the Last Glacial Maximum. Uncertainties in delta age depend on both the accuracy of densification models and the accuracy of parameters needed to use the models. Uncertainty due to correlation can be very low for high-resolution records with abrupt transitions like the methane variations related to D–O events (Figure 2), but records with very low-frequency variability and/or low resolution can result in larger correlation errors.

One other specific correlation tool uses the accumulation of cosmogenic ^{10}Be in polar ice. ^{10}Be (half-life = 1.36×10^6 years) is produced in the stratosphere by interactions of cosmic ray

neutrons with atmospheric molecules. ^{10}Be is particle reactive and quickly scavenged and removed to the earth surface. The flux of ^{10}Be is controlled by the primary cosmic ray flux (assumed constant on the time scales of interest), and modulation of the flux by changes in the earth's magnetic field strength and solar activity. It is expected that excursions in the modulation effects create globally synchronous changes in ^{10}Be flux to polar regions. One well-known excursion that has been used for correlation is the '40 ka' event, an interval of significantly enhanced ^{10}Be deposition found in Antarctic and Arctic ice cores, associated with the Laschamp geomagnetic excursion (Blunier et al., 1998; Raisbeck et al., 2002). Smaller scale variations in ^{10}Be associated with solar variability have also proved useful (Taylor et al., 2004).

Comparing Greenlandic and Antarctic Ice Core Records on Common Chronologies

In the first study of this type Bender et al. (1994) compared stable isotope records from GISP2 (Greenland) and Vostok (Antarctica) on a common chronology constructed using $\delta^{18}\text{O}_{\text{atm}}$ as a stratigraphic correlation tool. $\delta^{18}\text{O}_{\text{atm}}$ varies with time because the oxygen isotopic composition of the atmosphere is controlled by the ocean isotopic composition through the cycling of oxygen between the atmosphere and ocean by photosynthesis and respiration. $\delta^{18}\text{O}_{\text{atm}}$ is also secondarily influenced by processes in the terrestrial biosphere. The lifetime of oxygen in the atmosphere with respect to these processes is ~ 1000 years (Bender et al., 1994) – as a result $\delta^{18}\text{O}_{\text{atm}}$ variations are globally synchronous, but relatively slow (Figure 2). Bender et al. estimated that the precision of their comparison between GISP2 and Vostok was ~ 3000 years, due to analytical uncertainties, uncertainty in correlation, and uncertainty in delta age (primarily for Vostok). Their main observation was that long D–O events in Greenland had counterparts in Antarctica, but that uncertainties in their study were too large to discern if these events were temporally in or out of phase. A later study (Bender et al., 1999) revisited the GISP2–Vostok comparison with a higher precision data set. This study confirmed the link between long Greenland D–O and Antarctic warm events, and suggested that shorter Greenland D–O events also had Antarctic counterparts. As in the previous study, temporal phasing was difficult to establish, but they suggested that the timing of peak warming in both hemispheres was similar, a conclusion supported by later work (see below).

Sowers and Bender (1995) performed a similar study for the deglacial section of the Byrd (Antarctica) ice core and showed that the Antarctic cold reversal (ACR), a cool interval that interrupted deglacial warming about 15 000 years ago, occurred at the time of abrupt warming (onset of the Bølling period) in Greenland, and that the subsequent cooling in Greenland (the Younger Dryas) corresponded with warming in Antarctica. Ice accumulation rates at Byrd are $\sim 5\times$ than at Vostok, making delta age smaller, and these conclusions are more robust than those for the Greenland–Vostok comparison.

Correlation using $\delta^{18}\text{O}_{\text{atm}}$ has the disadvantage that the low-amplitude variability creates relatively large uncertainties for some time intervals. Methane variations are more rapid (Brook et al., 1996) and this recognition led to studies using

methane as a correlation tool. For example, Blunier et al. (1998) used methane for correlating stable isotope records from the GRIP (Greenland) and Byrd ice cores over the time period from 10 000 to 50 000 years. The high-frequency methane variations over this time period (Figure 2), and lower delta age at Byrd versus Vostok (due to higher temperatures and accumulation rates), allowed a more precise comparison of isotope records between the hemispheres. Blunier et al. found that two prominent interstadial events in Greenland (D–O events 8 and 12) were preceded by warming in Antarctica by 2–3 ka, and over the 23 000–47 000 year time period the average phase relationship was Antarctica leading Greenland by 1000–2500 years. As these phase differences are large with respect to the various relative chronological uncertainties, they are robust. Blunier et al. also compared the Vostok record with GRIP, and came to similar conclusions as those based on the Byrd record. As discussed above, delta age is very large at Vostok, making definitive conclusions about phasing more difficult. However, Blunier et al. were able to verify their Vostok chronology at $\sim 40 000$ years by showing that ^{10}Be records from GRIP and Vostok matched for this time.

Blunier and Brook (2001) followed this work with a more comprehensive comparison of GISP2 and GRIP with Byrd, also based on methane, for the period 10 000–90 000 years. This comparison (Figure 3) showed that all seven of the larger/longer interstadial events in Greenland over this time period were preceded by warming events in Antarctica (numbered A1–A7) (Figure 3).

The total uncertainty in the relative chronology between the Byrd and Greenland records is between 300 and 500 years. Close visual comparison of the two records provides some further support for the suggestion that the 'out of phase' relationship between the Greenlandic and Antarctic records extends to the smaller D–O events and corresponding warmings in Antarctica. Blunier and Brook noted this relationship but cautioned that chronological uncertainties made it difficult to interpret. Taking advantage of new ice core records, EPICA Community Members et al. (2006) undertook an analogous study using the NGRIP (Greenland) and EPICA Dronning Maud Land (EDML) (Antarctica) ice cores, covering the last 120 000 years. Those authors concluded that not only did the onset of the 'A' events precede warming in Greenland, but they suggested that every Greenland interstadial event was preceded by a warm event in Antarctica.

One of the open questions from the above work concerns the precise timing of the onset of warming in Greenland versus the maximum warmth in Antarctica. 'Seesaw' models based on changes in North Atlantic ocean circulation and deep water formation predict that the maximum Antarctic warmth (and subsequent start of cooling) will lag or be coincident with abrupt warming in the south. This relationship is difficult to test as it requires very precise age control. Morgan et al. (2002) attempted such a test using data from the Law Dome ice core in Antarctica, and the GRIP core in Greenland, for the last deglaciation (between 11 000 and 17 000 years ago). Law Dome, in coastal east Antarctica, is an excellent location for this work due to high snow accumulation rates and relatively warm temperatures. During the time period covered by this study, Antarctic warming started at about 17 000 years ago, and as described above was interrupted at about 14 000–15 000 years by the

Figure 3 Comparison of stable isotope records from the GISP2 and Byrd ice cores on a common chronology created using methane concentration variations (also shown). The large oscillations in isotope ratios in Greenland represent temperature changes of $>10^{\circ}\text{C}$. The more modest Antarctic isotopic fluctuations probably represent a few degrees of temperature change. Reproduced from [Blunier T and Brook EJ \(2001\)](#) Timing of millennial-scale climate change in Antarctica and Greenland during the last glacial period. *Science* 291: 109–112.

ACR ([Figure 3](#)). In the standard seesaw model, the ACR corresponds to the warming during the Bølling and Ållerød periods in the Northern Hemisphere, and the cold Younger Dryas that followed occurred at a time of strong warming in Antarctica ([Figure 3](#)). Using methane as a stratigraphic marker, Morgan et al. inferred that the start of the ACR preceded the onset of the Bølling period, a relationship that is inconsistent with the standard seesaw concept. At the limits of their uncertainties, the Morgan et al. data allow the onset of the ACR onset to be synchronous with Bølling warming, but they viewed this scenario as unlikely. Later work creating a composite Antarctic temperature record ([Pedro et al., 2011](#)) suggests that regional climate variability contributed to the early cooling at Law Dome, and the composite record suggests that the ACR is synchronous with the Younger Dryas.

[Brook et al. \(2005\)](#) examined the timing of Antarctic events in the Siple Dome ice core (west Antarctica) and compared Siple Dome to both Byrd and GISP2 for the 8700–56 000-year period. Conditions at Siple Dome are similar to that at Byrd, resulting in a record with comparable time resolution and precision of comparison. The results are similar to those of [Blunier and Brook \(2001\)](#) for the larger D–O/Antarctic event pairs in this time interval. No strongly consistent relationships for the smaller D–O events and Antarctic climate is evident, although the seesaw pattern is apparent for some time intervals.

In a variant of the above studies, [Delmotte et al. \(2004\)](#) used a high-resolution 440 000-year methane record from the Vostok ice core as a proxy for Greenland climate variations, and compared the timing of methane variations with the timing of temperature change in Antarctica via the Vostok stable isotope record. This approach is justified based on several studies that show an extremely close relationship between methane

variations and Greenland temperature variations (e.g., [Severinghaus and Brook, 1999](#); [Severinghaus et al., 1998](#)). Using a lagged correlation analysis, Delmotte et al. showed that methane consistently lagged the δD temperature proxy in the Vostok record, by an average of 1100 ± 200 years, which suggests that the seesaw pattern in Antarctic and Greenlandic temperatures is persistent feature of late Quaternary climate change. [Loulergue et al. \(2008\)](#) reported a more detailed record and analysis of similar variations covering the last 800 000 years.

One study has suggested an exception to the seesaw pattern. [Steig et al. \(1998\)](#) used methane and $\delta^{18}\text{O}_{\text{atm}}$ to create a chronology for the Taylor Dome ice core in east Antarctica for the last deglaciation. In that chronology, a small cooling trend at Taylor Dome seems to correlate best with the Younger Dryas period in Greenland, and the main Antarctic deglacial warming seems to correlate best with the abrupt warming at the start of the Bølling period in Greenland. In all other Antarctic records, deglacial warming started at about 17 000 years (see [Figure 3](#)) well before the main Greenland warming. Taylor Dome is glaciologically unusual though, and [Mulvaney et al. \(2000\)](#) suggested that extremely low accumulation rates at Taylor Dome at the end of the Ice Age, unrecognized by Steig et al., might explain an apparent synchrony between Taylor Dome and Greenland records.

A weakness of the gas-based chronologies is reliance on models for delta age, although models are improving in sophistication ([Goujon et al., 2003](#)). In some cases, verification of the delta age model is possible through the use of nitrogen and argon isotope proxies for temperature change ([Caillon et al., 2003](#); [Huber et al., 2006](#); [Severinghaus and Brook, 1999](#); [Severinghaus et al., 1998](#)). Abrupt temperature changes cause a detectable fractionation of nitrogen and argon

isotopes due to thermal diffusion in the snowpack. In favorable circumstances, this signal is preserved in the gas phase in ice cores, and provides a record of the timing of abrupt temperature change that can be directly compared to changes in other gases (e.g., methane). One main conclusion from these studies has been that abrupt changes in temperature in Greenland coincide very closely with abrupt changes in atmospheric methane. Delta age models are generally able to reproduce the timing indicated by the thermal fractionation studies, reducing uncertainty in this aspect of the inter-polar comparison between ice cores. Unfortunately, thermal fractionation records from Antarctic ice cores are rare, though not unknown (Caillon et al., 2003) because temperature changes are often small and/or slow to be recorded by this proxy.

Statistics of Inter-polar Comparisons

Conceptual and numerical models attribute warming of high southern latitudes at times when Greenland cooled to decreases in the North Atlantic overturning circulation, which diminished heat transport to high northern latitudes while leaving more heat in the Southern Hemisphere (e.g., Crowley, 1992; Ganopolski and Rahmstorf, 2001; Knutti et al., 2004; Menviel et al., 2008; Schmittner et al., 2003; Stocker, 2002; Stocker et al., 1992; Vellinga and Wood, 2002). The Antarctic–Greenland comparison has been used to support this mechanism of abrupt climate change.

A variety of quantitative analyses have been applied to the data sets discussed here with varying conclusions. Steig and Alley (2002) used lag correlation analysis of filtered data to examine the relationships between Byrd and GISP2. They concluded that the data are consistent with either a Southern Hemisphere lead of 1000–1600 years or a 400–800-year Southern Hemisphere lag, and emphasized that neither is a complete description of the data. Schmittner et al. (2003), also using correlation analysis of filtered data, argued that temperature changes in Greenland led changes of the opposite sign in Antarctica. Their analysis also revealed high correlation for Antarctica leading Greenland by ~1300 years, but they emphasized that this observation need not require a trigger for abrupt climate change in the Southern Hemisphere. Huybers (2004), commenting on Schmittner et al., and using a different model analysis, argued that a small Antarctic lead was statistically superior to a Greenland lead. Wunsch (2003) analyzed the records in the frequency domain, and concluded that at periods longer than about 2500 years Antarctic temperature changes led those in Greenland by 1400–1800 years, but suggested that evidence for mechanistically significant relationships between the records on shorter time scales is weak or absent. Stocker and Johnsen (2003) developed a simple ‘thermal bipolar seesaw’ model which allowed them to predict the Byrd isotope curve fairly accurately from the Greenland (GRIP in this case) record by incorporating a heat reservoir (the Southern Ocean), which delays and integrates the impact of a Northern Hemisphere climate changes on the Southern Hemisphere. They argued that almost all D–O events between 25 and 65 ka have a recognizable counterpart in the Byrd record, an argument further developed by EPICA Community Members et al. (2006). Knutti et al. (2004) elaborated on this

approach with a more sophisticated model, and reached similar conclusions. Roe and Steig (2004) argued for a significant relationship between the Byrd and GISP2 records, but only for the largest and longest of the millennial-scale fluctuations, consistent with the visual interpretation of the data described above. In summary, there is consensus that the largest of the D–O events were preceded by Antarctic warming, and that the Antarctic warming terminated at about the time of abrupt warming in Greenland. Cooling then followed in both locations (Figure 3). The Byrd, Vostok, and, EDML records appear to show similar patterns for shorter events, but not all approaches to analyzing the statistical robustness of this observation come to the same conclusion. Long Antarctic records with higher accumulation rate than the Byrd ice core would be helpful. A suitable new core in West Antarctica (WAIS Divide ice core) was collected in the period from 2006 to 2011 and may help to address these questions once analyzed.

Implications and Directions for Future Work

As described previously the seesaw pattern observed for the larger D–O/Antarctic event pairs has been used as evidence for a major role for changes in thermohaline circulation in the origin of D–O events. In fact, the concept (if not the name) of the bipolar seesaw predates the detailed comparison of ice core records from Greenland and Antarctica, and arose originally from theoretical considerations of how reductions in the Atlantic deep overturning circulation should cause warming in southern latitudes (Crowley, 1992). Broecker (1998) coined the ‘seesaw’ term in explaining a mechanism for linking northern cooling and southern warming.

A number of these modeling studies reproduce the seesaw pattern by forcing changes in Atlantic Ocean meridional overturning circulation through a variety of means, and thereby reducing the northward transfer of heat in the North Atlantic region. Models applied to this problem range from simple conceptual models (Stocker and Johnsen, 2003) to coupled ocean atmosphere general circulation models (GCMs) (Vellinga and Wood, 2002). The result is often, though not universally, a warming in the Southern Hemisphere in the region of the Antarctic continent, although (consistent with the data) the response is not of equal magnitude to cooling in the north Atlantic.

To the extent that these models can reproduce the seesaw pattern they support the role of changes in North Atlantic overturning circulation in abrupt climate change. However, the exact mechanisms involved are not clear, and may not be represented properly in all models. For example, some studies have emphasized the possible role of key mechanisms in the southern ocean that might control the seesaw pattern, including sea ice formation and eddy mixing processes (Keeling and Stevens, 2001; Keeling and Visbeck, 2005).

Further understanding of the bipolar seesaw and related phenomenon requires work in several areas. New ice core records from sites with high accumulation rates are particularly important, as these reduce uncertainty in delta age, and may allow definitive constraints on the timing of the ‘tipping’ point of the seesaw mechanism. A wider spatial distribution of cores in Antarctica is also desirable since it is not clear where the

fulcrum of the seesaw is. Locating the fulcrum is important as it can help to distinguish between various mechanisms that cause Antarctic warming in models.

The chronologies used to interpret the bipolar comparison of ice core records can also be improved in a variety of ways. One is by the use of multiple constraints (various gases, ^{10}Be , etc.) in correlation schemes. Objective error analysis, for example using Monte Carlo simulations is also desirable. Lemieux-Dudon et al. (2010) present an example of this type of comprehensive approach. Delta age models are improving, and increasing our understanding of their reliability over the broad spectrum of accumulation/temperature conditions of glacial–interglacial climate cycles is important. Higher resolution, and higher precision, gas data will also be critical as uncertainty simply related to sample spacing and analytical error limits conclusions of some recent studies. New measurement techniques that can provide nearly continuous gas data will be particularly useful. Statistical analysis of these records can also be improved, and attention should be paid to developing objective analysis of the timing of Greenland warming/Antarctic cooling.

Introduction

The large polar ice sheets are rich archives of information on the climate and environment during the past ~800 000 years as demonstrated by the results of the deep ice core drilling programs in central Greenland (e.g., Andersen et al., 2004) and Antarctica (e.g., Augustin et al., 2004). The ancient ice found at depth in the central regions of the ice sheets can also be retrieved at the surface at certain locations along the ice sheet margin (e.g., Lorius, 1968; Reeh et al., 1991). This is illustrated by Figure 1, which shows particle paths in a cross-section of an ice sheet. The higher the ice was originally deposited in the accumulation area, the deeper into the ice sheet it will sink, and the nearer to the ice edge it will resurface in the ablation area. If basal temperatures never reached the melting point, and if basal ice was never subject to folding or faulting, a complete sequence of all deposited layers would occur at the surface in the ablation area with the oldest ice closest to the ice edge. In this way, collecting a 'horizontal ice core' at the ice-margin surface becomes possible.

Several different types of ice-margin sites from which records have been collected can be identified. The Greenland horizontal ice-coring sites (Figure 2) are land-based ice-margin sectors within the ice ablation zone where ice flow stagnates (typically due to a topographical obstacle, such as a ridge). Reeh et al. (2002) present a comprehensive overview of Greenland ice-margin sampling sites. In the summer, the surface of such ice margins consists of glacier ice that ablates by melting. The annual ablation rate at such sites ranges from near zero at the high altitude sites in North-East Greenland (e.g., Grandjean Fjord and Dronning Louise Land) to 1–3 m of ice at the sites at lower latitude and elevation (e.g., Pakitsoq). Surface irregularities with wavelength and wave height of typically 2–5 and 0.5 m, respectively, are a common occurrence. Supraglacial streams and lakes are also common. A photo of a typical Greenland ice-margin site is shown in Figure 3.

Another type of ice-margin site, known as a blue ice area (BIA), occurs in Antarctica (Figure 4). As the name suggests, BIAs are areas where bare glacier ice is exposed at the surface, often making the surface appear blue. The ice dynamics and climatology of Antarctic BIAs has been described in detail by Bintanja (1999). In contrast to the Greenland sites, ice ablates by sublimation rather than by melting. Ablation rates depend on local climatology and range between near zero and 35 cm water equivalent per year. BIAs most often exist in the lee of mountain ranges and nunataks, which act as barriers for snowdrift and cause stagnating ice flow as well. BIAs have substantially lower albedo, are warmer, and typically have gustier winds than the adjacent snow-covered areas (Bintanja, 1999). As a result of sublimation, the surface of BIAs is generally smooth but often rippled. Figure 5 shows a typical Antarctic BIA.

One final type of ice-margin site discussed here is an Antarctic valley glacier in which bare ice is exposed at the surface. They are Type II BIAs according to the classification of Bintanja (1999). On these glaciers, strong katabatic winds remove snow from the surface and induce ice sublimation. In contrast to the BIAs described in the above paragraph, the ice flow in these valley glaciers is not stagnated by topographic obstacles. Several such glaciers exist in the Dry Valleys region of Antarctica (Figure 6).

The Norwegian–British–Swedish Antarctic expedition of 1949–52 was the first to investigate ice-margin areas. These glaciological and geomorphological investigations took place in Dronning Maud Land (Bintanja, 1999 and references therein). In the mid-1960s, the first two shallow ice cores from an ice-margin area were drilled by a French expedition near the Dumont D'Urville station in the Terre Adelie coastal region (Lorius, 1968). Analyses of these ice cores were interpreted to suggest that some of the near-surface ice at this location was formed far from the coast. In 1969, the first meteorites were discovered on the surface of the Yamato Mountains BIA, dramatically increasing scientific interest in ice-margin sites (Yoshida et al., 1971). By the 1970s, the first water isotope, and even gas, records were being produced from Arctic ice-margin sites as well (Hooke, 1976).

Scientific interest in records from ice-sheet margins continues to increase, for several reasons. First, and most importantly, ice margins expose ancient ice at, or near, the surface. Deep ice-core drilling has the advantage of producing a stratigraphically ordered paleoenvironmental record that can be dated in a reliable way. However, deep ice-core drilling is very expensive and logistically challenging. Ice margins offer an opportunity to collect ancient ice much more easily and with orders of magnitude less expense. In addition, ice-margin outcrops can offer a virtually unlimited amount of ancient ice of a given age, making possible analyses of ultra-trace components that are not feasible in a conventional ice core. Second, Antarctic BIAs have proven to be the best meteorite collection sites in the world. Third, ice-margin records can offer insight into ice-sheet dynamics. Finally, ice-margin sites may contain the oldest ice on Earth.

Meteorites

More than 25 000 meteorites have been found on Antarctic BIAs (Harvey, 2003). Meteorites that fall in the snow accumulation zone of the BIAs are incorporated in the ice and carried with the ice flow to the BIAs. Since at many BIAs the ice flow stagnates and the ice is removed only by sublimation of the surface, the embedded meteorites are exposed and accumulate on the surface (Whillans and Cassidy, 1983). Meteorites from Antarctic BIAs have provided us with a wealth of scientific

Figure 1 Cross-section of ice sheet, showing particle paths connecting snow deposition sites in the accumulation zone with locations where the ice resurfaces in the ablation zone. information on extraterrestrial material, such as its geochemical composition and the size distribution of material reaching the Earth's surface, as well as estimates of the influx rate of extraterrestrial material (e.g., Harvey, 2003; Whillans and Cassidy, 1983; Yoshida et al., 1971). Meteorites may also be able to provide information about the age of ice exposed at the BIAs (e.g., Curzio et al., 2008; Nishiizumi et al., 1983 and

references therein). For example, cosmogenic isotope dating of a layer of debris thought to be of meteoritic origin within the ice at the Allan Hills BIA suggested an age as old as 2.8 My (Harvey et al., 1998). While a more detailed discussion of meteorites at Antarctic BIAs is outside the scope of this article, the interested reader could find a review of the topic in Harvey (2003).

Volcanic Tephra Layers

Many Antarctic BIAs contain well-defined outcropping tephra layers (e.g., Curzio et al., 2008; Nishio et al., 1985). There are a number of active volcanoes located in West Antarctica as well as in Victoria Land. Ash from eruptions can be deposited anywhere in Antarctica, become embedded in the ice and advected with the ice flow. Tephra layers have been found in all Antarctic deep ice cores (e.g., Dunbar et al., 2003; Fujii et al., 1999; Palais, 1985). Ice advection to the BIAs can result in exposure of tephra layers at the surface at these sites. Tephra layers have been documented at Mount Moulton (Dunbar et al., 2008; Wilch et al., 1999), Frontier Mountain and Lichen Hills (Curzio et al., 2008; Perchiazzi et al., 1999), Yamato Mountains (Katsushima et al., 1984; Koeberl, 1990; Nishio et al., 1985), Allan Hills (Harvey et al., 1998; Marvin, 1986), Lewis Cliff (Koeberl et al., 1988), and Skelton Neve and Kempe Glacier (Keys et al., 1977).

Studies of tephra layers at ice-margin sites can yield a variety of valuable information. Grain size can be used to infer distance from the source eruption (e.g., Nishio et al., 1985). Geochemical composition of the ash can be used to identify the volcanic area of provenance or sometimes even the individual volcano (e.g., Perchiazzi et al., 1999; Wilch et al., 1999). The age of the ash layer can be determined using the $^{40}\text{Ar}/^{39}\text{Ar}$ technique (e.g., Curzio et al., 2008; Dunbar et al., 2008; Wilch et al., 1999). In this way, ice-margin tephra layers can potentially be used to reconstruct the volcanic history of a region (Curzio et al., 2008).

With the application of the $^{40}\text{Ar}/^{39}\text{Ar}$ technique, tephra layers can also provide absolute age stratigraphic markers for the outcropping ice itself. While ice-margin sites present many advantages over ice cores as described above (e.g., cost-effective, unlimited ice amount), one of the main

Figure 4 Map showing locations of Antarctic blue ice areas (BIAs). Reproduced from Bintanja R (1999) On the glaciological, meteorological, and climatological significance of Antarctic blue ice areas. *Reviews of Geophysics* 37: 337–359, with permission.

Figure 6 Shallow ice-core drilling on Taylor Glacier, Dry Valleys, Antarctica. Photo courtesy of Hinrich Schaefer.

disadvantages is that dating the ice in these outcrops is much more challenging. There is no well-defined ‘top’ or ‘bottom,’ there are no layers to count, and using a flow model to trace ice parcels back to the accumulation zone involves more uncertainties than modeling ice thinning in the deeper part of a conventional ice core. Multiple tephra layers outcropping at an ice-margin site allow this problem to be resolved.

Dunbar et al. (2008) and Wilch et al. (1999) studied the outcrop pattern of tephra layers at Mount Moulton, West Antarctica (Figure 7). $^{40}\text{Ar}/^{39}\text{Ar}$ dates on several tephra layers showed that ice between ~ 10 and 496 ka old was outcropping in stratigraphic order at this site. The $^{40}\text{Ar}/^{39}\text{Ar}$ dates showed

that the ice stratigraphy becomes progressively more compressed with age, similar to what is observed in conventional ice cores. The oldest tephra layer was dated at 495.6 ± 9.7 ka, making this the oldest known ice in West Antarctica, and thus, a very valuable archive for paleoenvironmental studies.

Curzio et al. (2008) analyzed $^{40}\text{Ar}/^{39}\text{Ar}$ in samples from two tephra layers at Frontier Mountain in northern Victoria Land, finding that the oldest ice at this BIA appears to be ~ 100 ka old, while $>90\%$ of the outcropping ice is younger than ~ 49 ka.

In addition to providing the absolute ages of the ice layers, tephra layers allow for easy visual identification and tracing

Figure 7 A map of the Mount Moulton BIA showing ablation rates, ice motion, and the outcropping tephra layers (gray lines) with $^{40}\text{Ar}/^{39}\text{Ar}$ dates for some of the layers. Reproduced from Dunbar NW, McIntosh WC, and Esser RP (2008) Physical setting and tephrochronology of the summit caldera ice record at Mount Moulton, West Antarctica. *Geological Society of America Bulletin* 120: 796–812, with permission.

of stratigraphic layers, even in areas where these layers have undergone deformation and folding (Figure 8).

Water Stable Isotope Records

$\delta^{18}\text{O}$ and δD of ice respond mostly to variations in local temperature, moisture sources, and seasonality of precipitation, and have always been some of the main and most informative measurements made in ice cores (e.g., Jouzel et al., 1997; Petit et al., 1999). A number of studies have measured $\delta^{18}\text{O}$ and δD at ice-margin sites, either in horizontal surface profiles or in shallow cores, providing information about ice provenance, age, and flow.

Antarctic Sites

The first water stable isotopic measurements at an ice margin were described by Lorius (1968) and came from two shallow (~100 m) cores collected in 1964–66 near the Dumont D’Urville station in Terre Adelie, East Antarctica (66°40’S, 140°01’E). It was found that δD showed near-surface values of ~–130‰ for the top ~1/3 of the core, then a transition to much more negative values (~–370‰) around mid-core, with low values continuing to the bottom. The isotopically light values in the lower part of these two cores were initially interpreted to be a result of ice that formed far inland and at much higher elevations. Subsequent work and further shallow core drilling in this area (Tison et al., 1993 and references therein), however, indicated that the very negative δD values were also the result of this ice having been deposited during the last glacial period, and much of the observed shift in δD with depth was a record of the glacial–interglacial climatic transition.

Faure and Buchanan (1987) collected ice surface samples each 100 m in a profile in the ice flow direction at Allan Hills (76°42.3’S; 159°24’E). The $\delta^{18}\text{O}$ values indicate that ice from both glacial and interglacial periods is represented along the profile (Figure 9). Groote (1990) reports results of $\delta^{18}\text{O}$ analyses of surface ice samples from three Antarctic BIAs. At Reckling Moraine (76°15’S; 158°40’E), near-surface ice samples were collected every 100 m in a transect across the moraine and the surrounding blue ice. Fluctuations in $\delta^{18}\text{O}$ of about 5‰ over short horizontal distances suggested that ice exposed at the surface originated in different glacial and interglacial periods. At Lewis Cliff Ice Tongue (84°17’S; 161°05’E), a 200-m transect was sampled every 10 m. The most negative $\delta^{18}\text{O}$ value of –58.8‰ would, under the present conditions, require the origin of the ice to be in the highest central part of East Antarctica, whereas a glacial period origin of the ice would allow a source area that was closer. From Allan Hills (76°43’S; 159°40’E) only four 1-m core samples were analyzed, that is, too few to allow conclusions about the origin of the ice in this area.

Taylor Glacier in the Dry Valleys area has an 80-km long ablation zone, exposing potentially the longest and highest-resolution ice-margin record. Aciego et al. (2007) collected surface ice samples along a 28-km long profile following approximately the center flow line on the glacier. Samples were collected at a resolution of 25–50 samples per kilometer and subsequently analyzed for $\delta^{18}\text{O}$ and δD . Figure 10 shows the Aciego et al. (2007) δD results from the Taylor Glacier profile together with the $\delta^{18}\text{O}$ data from the Taylor Dome ice core (Steig et al., 2000). Taylor Glacier ice has Taylor Dome as its source, and the two are thus expected to contain the same climatic record. Aciego et al. (2007) used a comparison of variations in their water isotopic record with the Taylor Dome record as well as a few measurements of $\delta^{18}\text{O}$ of atmospheric O_2 in the Taylor Glacier profile to construct an approximate age scale for the

sampled section, as shown in Figure 10. Based on this age scale, Taylor Glacier exposes ice with ages ranging from Holocene to >70 ka.

Greenland Sites

The vast majority of ice-margin water stable isotope records have been retrieved from Greenland sites. The first sampling campaign on the west Greenland ice margin (69.7° N, 50.1° W) took place in 1977–78, and two shallow cores (<100 m) and a 400-m surface profile oriented perpendicular to the ice margin were collected. The $\delta^{18}\text{O}$ results of the study (Clausen and Stauffer, 1988) showed that ice with low $\delta^{18}\text{O}$ characteristic of the cold glacial periods was outcropping nearest to the ice margin, while further away from the margin ice had higher $\delta^{18}\text{O}$ values characteristic of the warm interglacial periods. Both shallow cores contained the low- $\delta^{18}\text{O}$ ice near the bottom and the high- $\delta^{18}\text{O}$ ice in the upper sections. The $\delta^{18}\text{O}$ transition in all three records was similar in magnitude to that observed in Greenland deep ice cores. This transition occurred deeper in the core that was situated further away from the ice margin. These results were as expected for an ice-margin site with relatively undisturbed flow, where the oldest ice flows closest to bedrock and emerges nearest to the margin.

Between 1985 and 1994, the $\delta^{18}\text{O}$ distribution of the surface ice was studied at 15 different locations on the Greenland ice-sheet margin (Reeh et al., 2002; Figure 11). Ice samples were collected in profiles perpendicular to the ice margin. At some locations, two or more records were obtained along closely spaced parallel sampling profiles in order to study the reproducibility of the records. The sampling frequency ranged from spot sampling at distances between 1 and 100 m to continuous sampling (20 cm sample length) over a distance of more than 450 m. All together, 28 $\delta^{18}\text{O}$ -records were established, giving an overview of the origin of the ice presently exposed at the Greenland ice margin.

Pleistocene ice is missing at 7 of the 15 $\delta^{18}\text{O}$ -sampling sites: Hans Tausen ice cap and Flade Isblink in eastern North Greenland, Tuto Ramp and Nuna Ramp in Northwest Greenland, Dronning Louise Land in central East Greenland, and Sermilik and Nansen Halvø in Southeast Greenland (for locations, see map in Figure 2). The absence of Pleistocene ice at these sites can be explained in two ways: (1) the Pleistocene ice was removed by basal melting; (2) the ice margin retreated considerably during the Holocene Climatic Optimum, and the later readvance or build-up to the present configuration consisted of ice of local Holocene origin. Reeh et al. (2002) argue that, very likely, the latter explanation applies to Tuto Ramp, Hans Tausen ice cap, and Flade Isblink ice cap, whereas low

accumulation rates in North Greenland favoring basal melting may explain the missing Pleistocene ice in some records from North Greenland ice sheet margins. At the remaining eight Greenland ice-margin sites, a 350–1700 m-wide band of Pre-Holocene ice occurs next to the ice edge.

Several attempts have been made to correlate the Greenland ice-margin $\delta^{18}\text{O}$ records with deep ice-core records based on the comparison of characteristic $\delta^{18}\text{O}$ events in the ice margin and ice-core records (e.g., [Reeh et al., 1991, 1993](#)). A postulated chronology along the ice-margin records was then

established by using the ice-core timescale. An example is shown in [Figure 12](#) in which $\delta^{18}\text{O}$ records from the Pakitsoq and Storstrømmen ice margins are compared to the $\delta^{18}\text{O}$ records from Camp Century on the Northwest Greenland ice sheet, GRIP in the Summit area, and the local Renland ice cap in central East Greenland. A more reliable age scale has since then been established for the Pakitsoq site and it will be discussed in more detail in the section on gas measurements below.

Barnes Ice Cap

Several studies that included water stable isotopic measurements were conducted on the margin of the Barnes Ice Cap, Baffin Island, Canada. [Hooke \(1976\)](#) reported measurements on several samples collected at the surface or from shallow cores. The Barnes Ice Cap margin exposes a distinctive band of white, bubble-rich ice, which is both underlain and overlain by darker blue-gray ice layers. The white ice band yielded very low $\delta^{18}\text{O}$ values that were similar to glacial-period values from the Camp Century ice core, while the darker ice layers gave values more characteristic of the Holocene. [Hooke and Clausen \(1982\)](#) provided further $\delta^{18}\text{O}$ measurements confirming earlier results and suggested that the unusually large $\delta^{18}\text{O}$ shift observed between the postulated glacial and Holocene ice bands was due in part to a lower accumulation altitude for the Holocene-age ice. [Zdanowicz et al. \(2002\)](#) measured $\delta^{18}\text{O}$ in a 2000 m-long surface transect from the margin, capturing a well-resolved glacial-interglacial transition.

Gas Records

Early Work

Possibly the first systematic gas composition analyses on any type of glacier ice were carried out on margin ice from the Storbreen glacier in Norway ([Coachman et al., 1956](#)), although some even earlier attempts are mentioned by these authors. Ice was analyzed by dry extraction (ice shaving under vacuum) for nitrogen (N_2), oxygen (O_2) and carbon dioxide (CO_2) content. Subsequent work by some of the same authors ([Coachman et al., 1958a,b](#); [Scholander et al., 1962](#)) included analyses of argon (Ar) and even carbon-14 of CO_2 ($^{14}\text{CO}_2$) in very large samples from the Storbreen glacier ablation zone as well as in Greenland icebergs.

[Fireman and Norris \(1982\)](#) analyzed CO_2 , $^{14}\text{CO}_2$, O_2 , Ar, N_2 , $^{15}\text{N}/^{14}\text{N}$ of N_2 , and $^{40}\text{Ar}/^{36}\text{Ar}$ in samples from the Allan Hills. While the major gas (O_2 , Ar, and N_2) analyses yielded values very close to ambient atmospheric levels, there was considerable scatter in the CO_2 and $^{14}\text{CO}_2$ results.

In Situ Cosmogenic ^{14}C

^{14}C is produced from ^{16}O in near-surface ice by cosmic rays. Early efforts to measure ^{14}C (in CO_2) in ice from margin sites (e.g., [Scholander et al., 1962](#); [van de Wal et al., 1990](#)) did not take this into account and focused instead on trying to use $^{14}\text{CO}_2$ to date the ice. The ages obtained by this method were too young because of the cosmogenic ^{14}C contribution.

[Lal et al. \(1990\)](#) and [Lal et al. \(1987\)](#) were the first to systematically investigate *in situ* cosmogenic production of

Figure 13 ^{14}C content of ice samples from two locations within the Allan Hills BIA. Reproduced from [Lal D, Jull AJT, Donahue DJ, Burtner D, and Nishiizumi K \(1990\)](#) Polar ice ablation rates measured using *in situ* cosmogenic C-14. *Nature* 346: 350–352, with permission.

^{14}C in ice by fast neutrons. Ice samples from the Allan Hills BIA with depths between 0 and 60 cm below surface were analyzed for both $^{14}\text{CO}_2$ and ^{14}C of CO (^{14}CO), Figure 13. They found that the ^{14}C content of the samples was as expected based on theoretical *in situ* production estimates and decreased with depth as expected due to shielding from overlying ice. The cumulative amount of *in situ* ^{14}C at the surface depends on the ice ablation rate. The authors were therefore able to use their ^{14}C measurements to estimate the ablation rates at the two sites and found their estimates to be consistent with conventional stake measurements.

The Scharffenbergbotnen BIA ($74^\circ 34' 40''\text{S}$, $11^\circ 02' 58''\text{W}$) in Queen Maud Land, East Antarctica, has been the location of several *in situ* cosmogenic ^{14}C studies. This work also explored the possibility of using *in situ* ^{14}C to estimate ablation rates,

suggesting the use of ^{14}CO to correct for *in situ* $^{14}\text{CO}_2$, in the hope of determining the true paleoatmospheric $^{14}\text{CO}_2$ signal to date the ice (van Roijen et al., 1994, 1995). Later work at this site also investigated *in situ* ^{14}C production by negative muon capture (van der Borg et al., 2001; van der Kemp et al., 2002). Like fast neutrons, muons are also secondary cosmic particles that are produced in the Earth's atmosphere and have the potential to interact with ^{16}O nuclei. However, muons are able to penetrate considerably deeper into the ice than neutrons. The authors found evidence that ^{14}C in ice is indeed produced by both neutrons and muons.

While the pioneering *in situ* ^{14}C work described above demonstrated cosmogenic ^{14}C production in ice by both neutrons and muons, much remains to be understood. For example, there is considerable disagreement with regard to the

Figure 14 Comparison of GISP2 ice-core data with 2001 data from the Pakitsq ice margin, Greenland. (a) GISP2 $\delta^{18}\text{O}_{\text{ice}}$, $[\text{CH}_4]$, $\delta^{18}\text{O}_{\text{atm}}$, and $\delta^{15}\text{N}$ are shown on the ice timescale for comparison with Pakitsq ice. (b) Record from the 2001 trench sample profile at Pakitsq. partitioning of this ^{14}C between the CO and CO_2 phases. In addition, large uncertainties remain in estimates of ^{14}C production rates in ice.

The Pakitsq Ice-Margin Site

The ice-margin location that up to now has been studied in most detail is the Pakitsq ice margin in West Greenland (Figure 3; for location, see map in Figure 2). Studies at this site have been performed since 1985 (e.g., Reeh et al., 1987, 1991, 2002), providing information on $\delta^{18}\text{O}$ of surface ice, ice ablation, surface and bottom topography, and ice dynamics. The studies demonstrated that ice older than ~ 11.5 ka (Pre-Holocene ice) forms a ~ 500 m-wide band adjacent to the ice edge (Figure 11). Since 1992, the width of the Pre-Holocene ice band has diminished by $7\text{--}8$ m year^{-1} . In the same period, the ice thickness has decreased by almost 1 m year^{-1} , because ice ablation (~ 3 m year^{-1}) presently exceeds the vertical ice velocity supplying ice to the surface (~ 2 m year^{-1}). Visual inspection of shallow trenches cut into the ice indicate a $50\text{--}70^\circ$ dip of the stratigraphy.

In 2001, a major program was launched at the Pakitsq ice margin aimed at investigating the potential of this site as a source for recovery of very large-volume samples of uncontaminated, well-dated ancient ice (Petrenko et al., 2006). The main aim of the program was to obtain measurements of ^{14}C of methane ($^{14}\text{CH}_4$) in the ice and use these measurements to better understand changes in the global methane budget during the last glacial–interglacial transition. Meaningful $^{14}\text{CH}_4$ results required that the sampled ice be very well dated and that CH_4 in the ice was well preserved.

Dating of Pakitsq surface ice utilized a combination of $\delta^{18}\text{O}_{\text{ice}}$, $\delta^{18}\text{O}$ of O_2 ($\delta^{18}\text{O}_{\text{atm}}$), $\delta^{15}\text{N}$ of N_2 , and methane concentration ($[\text{CH}_4]$) measurements in near-surface sample profiles. These records were compared to the GISP2 ice-core record from Greenland Summit. An ice-sheet flow-line model (Reeh et al., 2002) predicts that Pakitsq ice dating to the last glacial termination originates near Greenland Summit, about 190 km south and 40 km west of the GISP2 site, making this a meaningful comparison.

Figure 14 compares $\delta^{18}\text{O}_{\text{ice}}$, $\delta^{18}\text{O}_{\text{atm}}$, $\delta^{15}\text{N}$ of N_2 , and $[\text{CH}_4]$ in samples collected in a short transect in 2001 at Pakitsq to GISP2 for the Younger Dryas (YD)–Preboreal (PB) transition. Figure 15 shows a record of $\delta^{15}\text{N}$ of N_2 and $[\text{CH}_4]$ from trench sample profiles taken in 2001–2003. As concluded by Petrenko et al. (2006), the unique combination of the four geochemical tracers presented in Figure 14 is evidence that the Pakitsq section contains a well-preserved YD–PB transition. Figure 15 demonstrates the ability to re-establish the position of YD ice each season, as well as the fact that Pakitsq gas records are reproducible from year to year, despite the ~ 3 m year^{-1} ablation rate.

The same four tracers as well as visual appearance of surface ice were also used to interpret Pakitsq surface ice stratigraphy and infer the three-dimensional structure of the layers (Schaefer et al., 2009). Figure 16 shows measurements on samples taken in three consecutive years in a longer horizontal transect at the Pakitsq site. The measurements showed that this transect crossed a syncline–anticline pair fold that contains multiple exposures of the YD and other climatic intervals dating to the glacial–interglacial transition. Measurements in another near-surface transect revealed that a layer of suspected

Figure 15 $\delta^{15}\text{N}$ of N_2 and $[\text{CH}_4]$ for 2001, 2002, and 2003 trench sample profiles from Pakitsq. Reproduced from Petrenko VV, Severinghaus JP, Brook EJ, Reeh N, and Schaefer H (2006) Gas records from the West Greenland ice margin covering the Last Glacial Termination: A horizontal ice core. *Quaternary Science Reviews* 25: 865–875, with permission.

Figure 16 $\delta^{18}\text{O}_{\text{ice}}$ profiles and gas records from the main study area at Pakitsoq. The Last Glacial Maximum (LGM) to Bolling-Allerod (BA) sequence (at ~15–20 m) shows increasing age toward the margin (to NW), whereas the BA to YD to PB sequence (at ~0–5 m) is reversed and increases in age away from the margin (to SE). The cartoon at the bottom schematically illustrates the folding of the ice layers and indicates approximate positions of syncline axis (SA) and anticline axis (AA), as well as age of surface ice. Reproduced from [Schaefer H, Petrenko VV, Brook EJ, et al. \(2009\)](#) Ice stratigraphy at the Pakitsoq ice margin, West Greenland, derived from gas records. *Journal of Glaciology* 55: 411–421.

Eemian ice immediately adjacent to the ice edge was actually of Holocene origin and part of a large-scale fold that exposed another outcrop of the glacial-interglacial transition.

$[\text{CH}_4]$ records from multiple transects at Pakitsoq revealed that $[\text{CH}_4]$ was well preserved in many ice sections, but was elevated in others ([Petrenko et al., 2006](#); [Schaefer et al., 2009](#)). Using ice from sections with well-preserved CH_4 , [Schaefer et al. \(2006\)](#) produced the first record of $\delta^{13}\text{C}$ of CH_4 spanning the YD–PB climatic transition ([Figure 17](#)). The large and rapid YD–PB warming was associated with a ~50% increase in atmospheric CH_4 , and there has been considerable debate regarding the causes of the CH_4 increase. The [Schaefer et al. \(2006\)](#) record provided evidence that the increase was likely due to increased CH_4 emissions from wetlands rather than marine methane clathrates. Using very large volumes of ice (~1000 kg per sample) from the same YD–PB section, [Petrenko et al. \(2009\)](#) measured $^{14}\text{CH}_4$ over this climatic transition. The measurements showed no large changes in ^{14}C of CH_4 over the transition despite the large increase in CH_4 concentration, arguing strongly against

major involvement of ‘old’ CH_4 sources such as marine clathrates.

Other Studies

Ice-margin records also contain information about the dynamics of the ice sheet regions upstream of the ice-margin sites from which the records are retrieved. This is because geochemical tracers in the ice, besides showing large temporal variations reflecting climate change, also display large, systematic spatial variations over the surface of the accumulation region. These tracers measured on ice samples from the ice margin can therefore be used to link the ice sample to a specific site in the accumulation region and a specific time of deposition, and thereby provide information on ice sheet dynamics along the travel path of the ice parcel. The idea of using trace substances to obtain the time and site of origin of ice-margin ice was first exploited by [Dansgaard \(1961\)](#), who related $\delta^{18}\text{O}$ of West Greenland icebergs to the $\delta^{18}\text{O}$

Figure 17 $[\text{CH}_4]$ (a), $\delta^{15}\text{N}$ of N_2 (b), and $\delta^{13}\text{CH}_4$ (c) from a Pakitsoq transect spanning the YD–PB transition (same transect as shown in Figures 14 and 15). Reproduced from Schaefer H, Whiticar MJ, Brook EJ, Petrenko VV, Ferretti DF, and Severinghaus JP (2006) Ice record of delta C-13 for atmospheric CH_4 across the Younger Dryas–Preboreal transition. *Science* 313: 1109–1112.

distribution of the surface snow in the accumulation area feeding the calving glaciers from which the icebergs had been detached. Reeh (1988) and Reeh et al. (2002) further advanced this work by combining isotope measurements with ice-flow model calculations to determine the location on the ice sheet where ice in the ice-margin record was originally deposited as snow.

It seems likely that ice-margin sites may contain the oldest glacial ice preserved on Earth. One possible example of this was mentioned briefly above for the Allan Hills BIA (Harvey et al., 1998). A more famous example is Beacon Valley in the Dry Valleys region of Antarctica, which contains ice that is covered by a thick layer of glacial till. The till surface contains contraction-crack polygons, and volcanic ash deposits have been found filling some of the contraction cracks (Sugden et al., 1995 and references therein). $^{40}\text{Ar}/^{39}\text{Ar}$ dating of these ash deposits yields ages near 8 My, suggesting that the ice may date as far back as the Miocene (Sugden et al., 1995). Cosmogenic nuclide dating of the surface till material has also suggested a very old minimum age for the buried ice of ~ 2.3 My (Schafer et al., 2000). However, other studies have suggested that the ice may be younger (e.g., Ng et al., 2005). It is hypothesized that the buried Beacon Valley ice was originally derived from an expanded Taylor Glacier. The till layer above the ice formed from entrained material that became exposed as the ice sublimated. As the till layer thickened, it dramatically reduced the ice sublimation rates, allowing this ice to persist for millions of years.

The extremely old margin ice has been of interest to biologists studying microbial survival in extreme environments. Bidle et al. (2007) analyzed five samples of ancient ice from Beacon Valley and the adjacent Mullins Valley for cell viability and state of community DNA. They found that, surprisingly, even ice thought to be ~ 8 My in age contained some viable microbes. The study found, however, that viability and DNA are compromised with age and suggested that average community DNA declines exponentially with a half-life of ~ 1.1 My. Another study included examination of a single sample of Beacon Valley ice, and found no evidence of bacterial survival (Johnson et al., 2007).

Outlook and Ongoing Work

The full potential of ice-margin sites as archives of easily accessible ice paleoenvironmental records is just beginning to be realized. Several exciting projects are in various stages of progress as of the time of this writing.

A horizontal ice-core record of $\delta^{18}\text{O}_{\text{ice}}$ has been recently measured for Mount Moulton (Popp et al., 2004). This record is constrained by radioisotopic $^{40}\text{Ar}/^{39}\text{Ar}$ dates on several ash layers in the ice, and includes the complete penultimate glacial–interglacial transition for the first time for West Antarctic ice.

A project to date the stratigraphy of the ~ 80 -km long ablation zone of Taylor Glacier is underway in the Dry Valleys, Antarctica. One of the main aims of the project is to establish a well-dated, easily accessible ice archive with Ice Ages between Holocene and >100 ka. This project also aims to use Taylor Glacier ice for constraining *in situ* cosmogenic ^{14}C production rates in ice, as well as for $^{13}\text{CH}_4$ and $^{14}\text{CH}_4$ paleoatmospheric reconstructions.

A similar effort is underway at the Allan Hills BIA, Antarctica. This project aims to establish a surface ice paleoarchive that could extend as far as 2.5 My back in time. A further project is attempting to more reliably date the buried ice in the Dry Valleys region, with the hope of extending the ice paleoarchive even further back in time.

Introduction

It came as a surprise, when in 1917, Chapman realized from some theoretical derivations, that there was a phenomenon of ‘thermal diffusion’, wherein diffusion is driven not by a concentration gradient, but by a temperature gradient (Chapman, 1917). A few years before that Enskog independently arrived at the same conclusion, however, being more mathematically oriented, he did not realize the importance of the new discovery for physics (Enskog, 1917). Chapman and Dootson performed an experiment in which they maintained a mixture of two gases in a temperature difference which made it separate slightly as predicted (Chapman and Dootson, 1917). Many researchers followed this pursuit, and measured thermal diffusion constants for various gas mixtures. They noted that predictions of the theory by Chapman and Enskog worked especially well for mixtures of noble gases. Overall, the theory was found to be very successful, and pointed to the severity of collisions between molecules as the underlying driver of thermal diffusion (Mason et al., 1966).

In 1998, Severinghaus and colleagues realized that heavy gas-isotopic enrichments in ice cores immediately following abrupt climate warmings were caused by thermal diffusion. Moreover, this previously unexplained small isotopic artifact provided a powerful means to reconstruct magnitudes of climate changes (Severinghaus et al., 1998; Severinghaus and Brook, 1999). If constants of thermal diffusion for species of interest in air are known, the magnitude of temperature difference that separated them can be reconstructed. These workers were able to place, for the first time, thermal diffusion-based quantitative constraints on the prominent Younger Dryas-Preboreal, and Bølling transitions manifested in fossil air from the Greenland Ice Sheet Project 2 (GISP2) ice core.

The importance of the thermal diffusion ice-core paleotemperature-change recorder was emphasized by Jouzel (1999) and Alley (2000), as the difficulties associated with the conventional water isotope thermometer in ice ($\delta^{18}\text{O}_{\text{ice}}$) called for an independent check of temperature-change estimations. The empirical calibration of the conventional $\delta^{18}\text{O}$ thermometer was likely variable, especially at times of abrupt transitions, when other factors affecting it were changing (seasonality of snowfall, changing moisture sources, etc.; Jouzel et al., 1997). The problems with the conventional thermometer were partly uncovered by the so-called borehole $\delta^{18}\text{O}$ calibration, which makes use of the known cold pulse measured today deep inside the ice sheet, that reflects how cold the ice sheet was during the last glacial period (Cuffey et al., 1995). Subsequent work proved that the thermal diffusion explanation of the isotope artifact was correct (e.g., Severinghaus et al., 2001), and allowed documentation of the magnitudes of a few additional prominent abrupt climate changes, such as those in

Greenland ~70 000 years before present (BP; Lang et al., 1999); 45 000 years BP (Landaï et al., 2004), and ~8000 years BP (Leuenberger et al., 1999).

Controls on Isotopic Composition of Ice-Core Air

Current atmosphere is preserved in the Greenland ice sheet as the interstitial spaces in densified snow at ~100-m depth are closed off, as has occurred previously. Prior to becoming entrapped in newly formed ice, the air is free to diffuse up to the surface and back. The diffusive environment allows for two important fractionation processes to occur: thermal diffusion (Severinghaus et al., 1998) and ‘gravitational settling’ (Craig et al., 1988).

Thermal diffusion takes place if the top boundary (surface) is warmer (or colder) than the bottom boundary (close-off depth). The nonequal temperature, in turn, originates from climate change, which affects the top boundary first. The composition of the enclosed air is then slightly offset from atmospheric air, because of the thermal diffusion process. In addition, there is a slight tendency of heavier species in air to settle down, hence the term gravitational settling (Schwander, 1989). The composition offset of the enclosed air caused by the two processes is typically small (<1%), and is best noticed in its stable isotopes, which can be measured with marked sensitivity by mass spectrometry.

Measuring the Thermal Diffusion Trace

To measure a trace of thermal diffusion, a piece of ice from known depth is obtained (e.g., from 1820 m depth at Greenland summit, which corresponds to 14 650 years of age for the enclosed gas), and fossil air is removed under vacuum (Severinghaus and Brook, 1999). The resulting air sample is passed through a mass spectrometer to measure stable isotope ratios, most notably nitrogen (N_2) and argon (Ar) that are abundant and unchanging in the atmosphere (the measured ratios are $^{29}\text{N}_2/^{28}\text{N}_2$ and $^{40}\text{Ar}/^{36}\text{Ar}$).

If the fossil air has undergone some gravitational fractionation of its isotopes, but has not been affected by thermal diffusion, any anomalies in nitrogen (29/28) will always be exactly equal to those in argon (40/36) divided by four. That is explained by the mass difference governing gravitational settling being the same in both cases:

$$\Delta M(^{29}\text{N}_2, ^{28}\text{N}_2) = \Delta M(^{40}\text{Ar}, ^{36}\text{Ar})/4 = 1 \text{ a.m.u.} \quad [1]$$

However, if thermal diffusion has played a role in fractionating isotopes in air, the anomaly in nitrogen (29/28) will be bigger than that in argon (40/36) divided by four. In fact, the difference of the two terms, usually close to zero unless thermal

Figure 1 (a) Measured profile of $\delta^{15}\text{N}$, $\delta^{40}\text{Ar}$, and other gases encompassing the depth interval 2584–2593 m in the GISP2 ice core (~69 000 years BP). (b) Measured profile of $\delta^{15}\text{N}$, $\delta^{40}\text{Ar}$, and other gases encompassing the depth interval 2600–2620 m in the GISP2 ice core (~73 000 years BP). (c) Derived profile of $\delta^{15}\text{N}_{\text{excess}}$ for the depth interval 2584–2593 m, constructed using the $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ data of (a). A small correction for gas loss is made to account for the fact that argon is slightly fractionated during the bubble close-off process and storage, hence 'gloss corr', or gas loss-corrected values (Grachev, 2004). (d) Derived profile of $\delta^{15}\text{N}_{\text{excess}}$ for the depth interval 2600–2620 m constructed using the $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ data of (b).

diffusion played a role, even if less important ‘bubble close-off’ fractionation processes have occurred (Severinghaus and Battle, 2006), serves as a marker of purely thermal diffusion fractionation:

$$\delta^{15}\text{N}_{\text{excess}} = \delta^{15}\text{N}_{\text{measured}} - \delta^{40}\text{Ar}_{\text{measured}}/4, \quad [2]$$

(Severinghaus and Brook, 1999), where the delta notation is employed: $\delta^{15}\text{N}_{\text{measured}} = [(^{29}\text{N}_2/^{28}\text{N}_2)_{\text{sample}}/(^{29}\text{N}_2/^{28}\text{N}_2)_{\text{reference}} - 1] \times 1000\text{‰}$, (one per mil unit (‰) is equal to 0.1% (reference may be defined as the measured ratio in current atmosphere)).

Laboratory experiments have shown that the sensitivity of $\delta^{15}\text{N}$ to thermal diffusion is $\sim 14.8 \times 10^{-3} \text{‰/°C}$, while that of argon is $40.4 \times 10^{-3} \text{‰/°C}$ (at an average temperature of -30°C ; Grachev and Severinghaus, 2003a,b). In other words, for example, the cold side of a vessel with air subjected to a 10°C temperature difference will be enriched by $\sim 0.0404\text{‰}$ in $\delta^{40}\text{Ar}$ relative to the warm side. Hence, the thermal diffusion sensitivity of the combined quantity $\delta^{15}\text{N}_{\text{excess}}$ of Eq. 2 can be found as follows:

$$\begin{aligned} \Omega(\delta^{15}\text{N}_{\text{excess}}) &= 14.8 \times 10^{-3} - 40.4 \times 10^{-3}/4 \\ &= 4.7 \times 10^{-3} \text{‰/°C}, \end{aligned} \quad [3]$$

which is in essence the calibration of the thermal diffusion paleotemperature-change recorder, constant through time.

Interpretation of Observed Thermal Diffusion Trace

From the preceding section it follows, that if only the $\delta^{15}\text{N}$ of an ice sample is measured, it is not possible to determine how much of the measured fractionation is due to thermal diffusion. Alternatively, if both $\delta^{15}\text{N}$ and $\delta^{40}\text{Ar}$ are measured, the calculated nonzero $\delta^{15}\text{N}_{\text{excess}}$ is purely the result of thermal diffusion. Moreover, if, for example, a value of $\delta^{15}\text{N}_{\text{excess}}$ on an ice sample of a certain age of $47 \times 10^{-3}\text{‰}$ is determined, it can be inferred that a climate change occurred at that time, with a deduced magnitude of:

$$\begin{aligned} \Delta T &= \delta^{15}\text{N}_{\text{excess}}/\Omega(\delta^{15}\text{N}_{\text{excess}}) \\ &= 47 \times 10^{-3} \text{‰}/4.7 \times 10^{-3} \text{‰/°C} = 10 \text{°C} \end{aligned} \quad [4]$$

Usually the isotopes are measured on a sequence of ice pieces, for example between 2584 m and 2593 meters depth in the Greenland GISP2 ice core, which allows a time profile of $\delta^{15}\text{N}_{\text{excess}}$ to be constructed (Figures 1a and b; Grachev, 2004). Such a profile serves several purposes: (i) it allows us to check whether the background value of $\delta^{15}\text{N}_{\text{excess}}$ is at its ‘relaxed’ zero value, or is somewhat offset, perhaps not having fully recovered from a preceding climate change; (ii) the maximum of the $\delta^{15}\text{N}_{\text{excess}}$ peak can be found; (iii) it can be determined at exactly what depth the abrupt warming sets in. Relating to the last point, an important comparison of $\delta^{15}\text{N}_{\text{excess}}$ with CH_4 measurements in ice fossil air allows us to decipher which region was first to change directly: the tropics, which presumably generate large proportions of atmospheric methane at glacial times, or Greenland temperature, suggesting mechanisms of abrupt climate change (Figure 2; Severinghaus and Brook, 1999).

Figure 2 Climate warming as reflected in N and Ar isotopes versus change in CH_4 at the Bölling transition ($\sim 14\,650$ years BP) (from Severinghaus and Brook, 1999; reproduced with permission). Direct comparison of the timing of change is possible, because the air age scale is the same for these indicators. The conventional ice water-isotope thermometer in the top panel serves well for reference however its age scale has to be adjusted (the so-called ‘gas age-ice age difference’ problem), and its empirical sensitivity coefficient to surface temperature has been found to vary markedly (Jouzel, 1999).

Direct Climate Change Reconstruction

A direct way of obtaining a climate-change reconstruction is to determine the magnitude of change in $\delta^{15}\text{N}_{\text{excess}}$ between the maximum of the peak and the baseline (Figures 1c and d). When the result is divided by the thermal diffusion sensitivity of $\delta^{15}\text{N}_{\text{excess}}$ of $4.7 \times 10^{-3} \text{‰/°C}$, it yields the approximated magnitude of the climate change. The actual climate change is usually best estimated at $\sim 1\text{--}3 \text{°C}$ above that value for central Greenland, because of the slow warming of the base of the firm that occurs in concert with thermal diffusion (e.g., Grachev and Severinghaus, 2005).

A direct thermal diffusion ice core reconstruction of an abrupt climate change can be performed according to the equation:

$$\begin{aligned} (\Delta T)_{\text{climate}} &= [\delta^{15}\text{N}_{\text{excess}}(\text{max}) \\ &\quad - \delta^{15}\text{N}_{\text{excess}}(\text{baseline})]/\Omega(\delta^{15}\text{N}_{\text{excess}}) \\ &\quad + (\sim 1 - 3 \text{°C heat correction}) \end{aligned} \quad [5]$$

(Figures 1c and d). It should be noted that the thermal diffusion recorder has been shown to work well for fast changes, such as the Dansgaard-Oeschger events of the last glacial period (Dansgaard et al., 1993). The reason is due to the requirement of a sustained temperature difference in the top portion of the ice sheet, where thermal diffusion proceeds and fractionates the air that subsequently becomes fossilized.

Introduction

To predict future changes to the Earth's climate, we need to understand the processes that control climate. Likewise, to understand how changes in the size of the Earth's ice sheets will influence sea level, we need to understand the processes that control the characteristics of the ice sheets. One way to improve our understanding of how these processes will operate in the future is to study how they operated in the past. To do this we need information about how and why climate and ice sheets have changed over time. Ice sheets and large glaciers contain an archive of ancient ice, dust, and trapped atmospheric gases. By analyzing these inclusions in ancient ice, we can determine how and why climate and ice sheets have changed in the past.

As snow falls on to the surface of an ice sheet, it compacts the snow below it, forming ice. Over millions of years the snow has built up into sheets over 4 km thick. The ice within the ice sheets flows both vertically and horizontally in response to gravity. In some locations, seasonal variations in the chemical and physical properties of the ice are preserved, allowing individual years to be identified as far back as 100 000 years ago. Ancient ice is most commonly collected by drilling into the ice and recovering ice cores, which are collected in metal cylinders from 3 to 30 cm in diameter ([Figure 1](#)). In rare locations, ancient ice is pushed to the surface with minimal distortion of the stratigraphy such that it can be directly sampled by trenching along the surface. The analysis and interpretation of such ice is done in the same manner as ice collected by coring.

Among the many contributions of ice core research to Quaternary Science, two stand out as having had the most

influence on our understanding of the climate system. The first demonstrates the tight link between the concentration of carbon dioxide in the atmosphere and surface temperature during the last 800 000 years ([Lüthi et al., 2008](#); [Petit et al., 1999](#); [Siegenthaler et al., 2005](#)). The second demonstrates that large climate change (e.g., change in surface temperature of 12 °C and 200% changes in precipitation) can occur in periods of less than a few decades ([Alley et al., 1993](#); [Siegenthaler et al., 1993](#); [Taylor et al., 1997](#)).

This article does not mention every ice-coring project; instead it focuses on efforts that were either pioneering in their approach or had a large influence on our understanding of climate ([Figure 2](#)). This article also does not include significant ice core research that has occurred outside of Greenland and Antarctica ([Thompson et al., 2003, 2005](#)). In reviewing the history of ice core science in Greenland and Antarctica, it is useful to divide the review into several periods.

Early Ice Core Projects

Prior to the early 1980s, ice core projects were not common and it was difficult to predict their outcome. The location of many of the early large ice-coring projects was selected to simplify logistics instead of optimizing the science. Despite this, the field was sufficiently new that such pioneering cores still produced significant results.

In 1954, Willi Dansgaard showed how the isotopic concentration of the oxygen entrapped in the ice could be used to determine the temperature history of the drill site ([Dansgaard, 1954](#)). In 1966, the Camp Century ice core was drilled in

northwest Greenland at an American military research site; yielding a low time resolution temperature record extending far enough into the past to show that the Greenland ice sheet did not completely melt during the last interglacial period (Dansgaard et al., 1969). Low time resolution, uncertainties about the dating of the core, and poor-understood ice flow limited the scientific value of the core. However, it demonstrated the potential of ice cores for climate research, thus enabling future projects to proceed.

The first deep Antarctic ice core was recovered at the American Byrd Station in 1968, which showed strong similarities with Northern Hemisphere records (Epstein et al., 1970). This core was also used in conjunction with later Greenland cores to investigate the relationship between climate changes in the Northern and Southern Hemisphere (Blunier et al., 1998).

In 1981, in a collaboration between Danish, Swiss, and American researchers, the Greenland ice sheet project (GISP), completed recovery of an ice core at Dye-3 in Southern Greenland (Langway and Oeschger, 1985). This well-dated record covered the last 90 000 years, and had sufficient time resolution to show warm interstadial events (referred to as Dansgaard/Oeschger events) of several thousand years' duration during the glacial period and abrupt changes in climate of 10–12 °C in less than a century (Dansgaard et al., 1989).

Figure 1 An ice core from a depth of 300 m from Siple Dome, Antarctica.

Concerns about the influence of ice flow and the lack of a replicate record reduced the widespread acceptance that this research deserved.

Recent Ice Core Projects

The previous ice cores led to wide acceptance of using ice core records to study climate phenomena. This enabled subsequent projects to obtain the resources needed to conduct field operations at sites selected to optimize the scientific value of the core, instead of at sites that were selected in part for their favorable logistics.

The evidence of rapid climate changes generated sufficient interest that two related Greenland ice core projects (GRIPs) were conducted to further investigate the Dye-3 results. After careful consideration, the optimal location for these projects was determined. The GRIP (involving eight European nations) and Greenland ice sheet project 2 (GISP2, involving 19 US institutions), completed field operations in central Greenland in 1992 and 1993, respectively (Hammer et al., 1998). Both of these projects used unique electromechanical drills that were raised and lowered with a wire line in an uncased hole. A petroleum-based drilling fluid was used to equilibrate the hydrostatic and pressure of the hole to prevent its collapse. The length of core section recovered on each drill run varied from 1 to 6 m. Designs based on the Danish ISTUK drill were developed for subsequent projects by European and other nations. The heavier US drill, which recovered a larger diameter core, was used on subsequent US projects.

The major outcome of the GRIP and GISP2 projects was the unquestionable confirmation of the Dansgaard/Oeschger events, and that many abrupt climate changes occurred during the glacial period, with temperature changes of up to 12 °C within a few decades (Siegenthaler et al., 1993) and factor of two changes in the ice accumulation rates (Alley et al., 1993). The Dansgaard/Oeschger events recorded in the ice cores were easily correlated to lower time resolution records of the same events in ocean cores (Bond et al., 1993). This greatly strengthened the concept that rapid reorganization of ocean circulation in the North Atlantic was a driving force of climate change.

Figure 2 Location of ice cores discussed in text.

In parallel with these Greenland projects, a continuing Russian effort of the Vostok coring site in Antarctic, with assistance in later years by France and the United States, extended the record of atmospheric greenhouse gases to 420 000 years. This record showed a tight link between changes in the atmospheric concentration of greenhouse gases and surface temperatures, and that the current concentrations and rate of increase of greenhouse gases is greater than at any time during the last 420 000 years (Petit et al., 1999). In 2002, the Japanese Dome Fuji core recovered a record similar to Vostok, confirming that the major characteristics of climate change for at least the last 340 000 years are similar throughout the East Antarctic Plateau (Watanabe et al., 2003). This project ultimately obtained a record that is about 720 000 years old (Motoyama, 2007).

Recovery of the Danish-lead North GRIP (NGRIP) was completed in 2003. This core contained discernable annual layers all the way to the bedrock, covering the last 100 000 years. The record shows that the last glacial period ended gradually over a period of 7000 years (North Greenland Ice Core Project Members, 2004).

Many intermediate-age cores have also been drilled in Antarctica. The Austrian-lead Law Dome project provided an exceptional record of atmospheric carbon dioxide during the last 2000 years (Etheridge et al., 1996; MacFarling Meure et al., 2006). The US-lead projects at Taylor Dome (Steig et al., 1998) and Siple Dome (Taylor et al., 2004) both yielded records extending to the beginning of the last glacial period, indicating large regional differences. However, ice flow makes their interpretation controversial and complete analysis of these records will require more ice cores. The British-lead Berkner Island project, in a region where climate is strongly influenced by the Atlantic Ocean, has been drilled and the initial results are available (Ruth et al., 2004). The International Trans-Antarctic Expedition has drilled an array of ice cores focusing on the last 200 years, with some cores extending to 2000 years BP. These short cores provide insights into the spatial patterns of climate change (Genthon et al., 2005).

Recovery of a core from Dome C in Antarctica was completed in 2005 (EPICA Community Members, 2004) by the European projects for ice coring in Antarctica (EPICA) consortium. Results from the upper portion of the core, spanning 740 000 years, show that the interglacial periods between 740 000 and 430 000 were cooler than more recent interglacials, and that a greater portion of each glacial cycle was spent in the warm mode. Marine Isotope Stage 11, which is often suggested as an analog to the current interglacial, persisted for 28 000 years, suggesting that current climate conditions will continue for an extended time unless altered by significant human activities. The core also showed that the strong relationship between greenhouse gases and Antarctic climate extends back through at least the last 800 000 years (Lüthi et al., 2008; Siegenthaler et al., 2005).

Recovery of a core from Dronning Maud Land, Antarctica, was completed in 2006 by the EPICA consortium, which has a well-dated chronology for the last 150 000 years (Ruth et al., 2007). This record will be exceptionally well suited for comparison with Greenland records, because the climate of both were strongly influenced by the Atlantic Ocean (EPICA Community Members, 2006). The Talos Dome deep ice core in East

Antarctica was drilled during the same period (2004–2007). It provided a precise, high-resolution chronology for the last 50 000 years (Buiron et al., 2011) and provides data through the last interglacial period. These new ice core records allow comparisons with other ice core records from Antarctica and Greenland at submillennial time scales (Masson-Delmotte et al., 2011; Stenni et al., 2011).

The US-led West Antarctic ice sheet (WAIS) divide ice core started field operations in 2005 and is expected to recover a record extending back about 60 000 years. This core will probably be the best Antarctic core for comparison with the Greenland cores, in determining the temporal relationship between Arctic and Antarctic climate changes. It will also provide an exceptionally high-resolution record of greenhouse gases extending into the last glaciation. A new drill that brings together many proven features from previous drills, and adds some new ones, was developed at the University of Wisconsin, Madison. This drill has separate down-hole motors for the drill cutters and a high-volume pump that collects the drill cuttings, high borehole travel speeds, and improved down-hole sensors and automatic control systems. The project will continue for several more years although the main coring was completed in 2011.

The Future of Polar Ice Core Research

In 2004, scientists from all the nations involved in major ice-coring programs, met to form the International Partners in Ice Core Sciences (IPICS), in order to develop plans for future international ice-coring efforts. Four projects had wide international support and are expected to proceed.

For the last 1 My, the climate has alternated between glacial and warmer conditions, approximately every 100 000 years. Prior to 1 Ma these shifts occurred approximately every 40 000 years. The cause of this change is probably related to changes in the carbon cycle. To improve our understanding of how the carbon cycle controls climate, we need to have a record of greenhouse gases and climate that extends at least 1.2 My into the past. This record can only be obtained from an Antarctic ice core drilled at a carefully selected location. It is envisioned that at least two cores will be drilled at locations that are likely to yield the longest possible ice core climate records from Antarctica. Preliminary site selection work indicates these sites are in East Antarctica and site selection activities started in 2007.

The last interglacial period ended 122 000 years ago. To understand how the climate might change at the end of the current interglacial, we need to have a better understanding of what happened when the last interglacial ended. Unfortunately, the existing Greenland ice cores do not contain a complete, high-quality record of this transition. The best Northern Hemisphere record of climate change can be developed from an ice core collected in northwest Greenland. Drilling for the North Greenland Eemian ice drilling (NEEM) project started in 2007 and reached bedrock in 2010. The first results from the NEEM project are already available (Steen-Larsen et al., 2011). Unlike the NGRIP core, this core may provide a complete, high-resolution Northern Hemisphere record of the last interglacial.

To understand the climatic teleconnections between different regions, we need a global array of climate records. One array will investigate the spatial response of climate to the changes that occurred from the end of the last glacial period to the present. This array will consist of existing cores and new ones. It is anticipated that several new cores, mostly in Antarctica, will be recovered to fill in this array. A new US deep-drilling project is ongoing at the West Antarctic ice sheet divide (WAIS-D) and the borehole reached 3330 m depth in 2011 after four drilling seasons. This WAIS-D deep ice core is expected to yield an annual-layer-counted chronology for the last 40 000 years and an undisturbed depth–age relationship that likely extends back about 60 000 years (Laird et al., 2010). Shallow ice cores drilled as part of the WAIS-D project have already yielded high-resolution records of atmospheric changes during the late Holocene (Kunasek et al., 2010; Lamarque et al., 2011; Mitchell et al., 2011).

To place the current climate change problem in perspective, and to understand the phenomena that influence today's climate, we need a better understanding of the spatial interaction of recent climate phenomena on timescales of decades and centuries. This can be accomplished by a global array of ice cores that span the last several millennia with annual or near-annual resolution. This array will consist of many existing cores, and it is anticipated that many new cores will be collected in polar and nonpolar regions to complete this array.

Dynamics of the Greenland Ice Sheet

C S Hvidberg, A Svensson, and S L Buchardt, University of Copenhagen, Copenhagen, Denmark

© 2013 Elsevier B.V. All rights reserved.

Introduction

The Greenland ice sheet is the largest ice sheet of the Northern Hemisphere (Figure 1). It covers about 80% of Greenland and has an area of $1.71 \times 10^6 \text{ km}^2$ and an average thickness of about 1.6 km. It covers a latitude span from 84° N near the northern margin in Peary Land, to 60° N at the southern tip: a length of about 2700 km. In Central Greenland at 72° N , its width from west to east is about 900 km. It contains a total volume of $2.95 \times 10^6 \text{ km}^3$ ice (Thomas and PARCA Investigators, 2001), enough to raise Earth's sea level by 6–7 m if it melted away completely. The Greenland ice sheet is the second largest ice sheet on Earth, exceeded only by the Antarctic ice sheet which has a volume that is about ten times larger than that of the Greenland ice sheet.

The Greenland ice sheet plays an important role in climate research. The ice sheet interacts dynamically with the atmosphere and ocean circulation in the North Atlantic, a region thought to play a key role in Earth's climate system. The Greenland ice sheet contains a unique record of past climate changes, and ice more than 100 000 years old has been recovered from deep ice cores drilled through the Greenland ice sheet (e.g., NorthGRIP Members, 2004). Because snow accumulation rates in the central areas have been sufficiently high, annual layers can be resolved far back into the last glacial period (Svensson et al., 2005), providing high-resolution climate records.

The Greenland ice sheet continues to evolve in response to changes in Earth's climate. Snow deposited in the interior is gradually transformed to ice, and layers of ice are thinned and stretched by ice sheet flow. Ice flows from the interior toward the margin where it is lost by surface melting or by discharge of ice into the ocean. Current observations of retreat along the margins and acceleration of outlet glaciers suggest that the ice sheet is currently reacting to a changing climate. Understanding the dynamics of the Greenland ice sheet is crucial for interpretation of the climate records obtained from ice cores, and for understanding the dynamical response of the ice sheet to climate change.

Surface and Basal Topography

The Greenland ice sheet is elongated in the north–south direction and configured with a central ridge running from south to north to about 77° N , connecting the two domes in South Greenland and in Central Greenland. The highest dome, Summit in Central Greenland, has an elevation of approximately 3200 m (near the deep drilling locations GRIP (Greenland Ice Core Project) and GISP2 (Greenland Ice Sheet Program 2)), and the other dome in South Greenland has an elevation of 2850 m (Bamber et al., 2001a; Figure 1). The saddle between the domes forms a distinct ridge with elevations of around 2500 m. North of Summit, the ridge widens as it continues

northwest. Near 77° N , it forks into a northern and western branch. About two-thirds of the Greenland ice sheet has surface elevations above 2000 m.

Overall, the bedrock is bowl shaped, with low central areas near sea level and coastal mountains with elevations of 1–3 km above sea level almost entirely surrounding it. The bedrock is mountainous in South Greenland and particularly in East Greenland where coastal mountains reach above 3 km above sea level. In West Greenland, the coastal mountains are lower than in the East. In South Greenland, bedrock elevations in the central areas are generally above 200 m above sea level. North of Summit, the bedrock in the central areas is generally smooth and the ice sheet is grounded near or below sea level, with widespread areas below sea level (Bamber et al., 2001b).

The ice thickness reaches a maximum of 3000–3300 m near the central north–south ridge between 70° and 75° N (Bamber et al., 2001b). The loading of ice has depressed the bedrock through isostatic adjustment of the lithosphere. If the ice were removed, and the bedrock allowed to rebound isostatically, the elevation of the central basin would be 600–800 m above sea level (Bamber et al., 2001b). The ice sheet fills the low central areas completely and flows toward the coast. The coastal mountains are cut by deep fjords where outlet glaciers reach the ocean and icebergs break off from floating glacier tongues. In North-West Greenland, the ice sheet extends to the ocean over a longer distance.

Surface and Basal Temperature

Over most of the ice sheet, the mean annual surface temperature is far below the freezing point. The high-elevation central areas have a mean annual temperature below -25° C , and surface melting occurs only rarely (dry-snow zone). At Summit, the mean annual temperature is -32° C . July is the warmest month, with a mean temperature of -12° C , and February is the coldest month, with a mean temperature of -42° C . In South Greenland, surface temperatures near the north–south ridge are -10 to -20° C . At Dye3, the mean annual temperature is -19° C , and surface melting occurs often during summer. At Dye3, meltwater percolates down into the firn and refreezes entirely to form ice layers in the firn (percolation zone). At lower elevations along the margin, surface meltwater forms drainage systems, and is eventually lost by runoff through surface streams and subglacial drainage systems (e.g., Cuffey and Paterson, 2010).

The ice temperature below the surface is determined by the downward advection of cold ice that is gradually heated by several processes. The geothermal heat flux is heating up the ice from beneath. The near surface firn layers may be heated by surface meltwater that percolates down into the firn and refreezes. The basal ice layers are heated by internal deformation of the ice and by frictional heating at the base if there is

basal sliding. The basal temperature near the north–south ridge is controlled by ice thickness, geothermal heat flux, and past surface temperature and accumulation that have determined the downward advection of cold ice due to flow through time. Under Summit, central Greenland, the basal temperature was measured to be -9.5°C in the GRIP borehole. The basal temperature is still affected by the cold glacial climate, and if the current climate had prevailed it would have been several degrees higher, maybe reached the melting point. The effect is complicated, as the glacial temperatures were colder, but at the same time accumulation rates were lower, thereby decreasing the downward advection. The ice free surface of Greenland consists mostly of old rocks with a low geothermal heat flux of $30\text{--}50\text{ mW m}^{-2}$ (e.g., Van der Veen, 1999). Using this geothermal heat flow, estimated basal temperatures are -5 to -10°C in the central areas. In Northern Greenland, widespread areas with basal melting have been identified by analyses of radar data (see section ‘Internal Stratigraphy’ below). These areas have a basal temperature at the pressure melting

point of -2 to -3°C (beneath 3 km of ice) (Dahl-Jensen et al., 2003), and the basal melting is due to a higher geothermal heat flux in these areas. In the NorthGRIP deep drilling borehole at the north-west ridge in North Greenland, the basal temperature was at the pressure melting point of -2.4°C , and the borehole drilling reached water-saturated sediments at the base beneath 3185 m of ice. Basal melting has been estimated to be 7 mm a^{-1} , and the geothermal heat flux has been estimated to be 130 mW m^{-2} (NorthGRIP Members, 2004).

Surface Mass Balance

A compilation of the accumulation rate for 1971–90 was presented by Bales et al. (2009; Figure 2). The average annual

Figure 1 Shaded relief plot of Greenland surface topography (Bamber et al., 2001a). White areas are ice-covered. Deep drilling sites are indicated, where ice cores have been drilled through the Greenland ice sheet to the bedrock. These sites are: Camp Century, Dye3, GISP2, GRIP, NorthGRIP, NEEM (North Greenland Eemian Ice Drilling) (for a historical overview, see Dansgaard, 2004; about NEEM, see Buchard and Dahl-Jensen, 2008). Summit, the highest dome on the Greenland ice sheet, is near the GISP2 and GRIP sites.

Figure 2 Accumulation map of Greenland. Reproduced from Bales RC, Shen D, Du G, et al. (2009) Annual accumulation for Greenland updated using ice core data developed during 2000–2006 and analysis of daily coastal meteorological data. *Journal of Geophysical Research, Atmospheres* 114: D06116, <http://dx.doi.org/10.1029/2008JD011208>. Contour and shading show accumulation rate in mm of water equivalent a^{-1} . Also shown for reference are the 1000, 2000, and 3000 m elevation contours.

accumulation rate is $0.3 \text{ m of water equivalent a}^{-1}$. The most important trend in accumulation rate is the south to north decrease with variations ranging from almost $1 \text{ m of water equivalent a}^{-1}$ in the south to below $0.1 \text{ m water equivalent a}^{-1}$ in the northeast. The north-south ridge forms a topographic barrier with significant effect on the accumulation rate pattern. In the south, weather systems traveling along the North-Atlantic storm track carry moisture and precipitation to the Greenland ice sheet. North of Summit, the accumulation rate gradually decreases with elevation on the western flank, but drops rather abruptly with a factor of two across the ridge.

Surface melting is widespread and occurs over about 50% of the Greenland ice sheet (Thomas and PARCA Investigators, 2001), but only a few measurements are available over both time and space. In addition to direct observations of surface melt and runoff, passive microwave data observed from satellite have been used to infer melt extent and duration. Ablation by melting and runoff has also been modeled by the positive degree day (PDD) approach or by energy balance models of the upper firn layer. PDD methods have been widely used to estimate surface melting, but it is based on an empirical relationship between surface temperature and melt that is based on present-day observations. Energy balance models consider the key physical processes, but require a large set of meteorological data as forcing (e.g., Van der Veen, 1999).

The line that separates the net accumulation zone from the net ablation zone is called the equilibrium line. In Greenland, the total accumulation of snow above the equilibrium line is approximately balanced by surface melting in the ablation zone and discharge of ice into the ocean. At the end of the summer, when fresh snow from the previous year has been removed by surface melting in the ablation zone, the surface of the ice sheet will consist of progressively younger ice inward from the margin toward the center. The oldest surface ice is found at the margin, and inland of the equilibrium line, the surface consists of snow from the previous year.

Discharge of Ice into the Ocean

Discharge of ice into the ocean constitutes an equally important contribution to the mass loss of the Greenland ice sheet as surface melting (van den Broeke et al., 2009). The discharge consists partly of calving of icebergs, and partly of melting from beneath floating ice margins. Near the margin, ice flow rates vary significantly spatially. The ice sheet drains through many fast-flowing outlet glaciers and ice streams in valleys in the coastal mountains, and these fast-flowing areas are separated by areas of slow flow (Figure 3; Joughin et al., 2010). Several glaciers drain into fiords, and produce icebergs from floating glacier tongues. The ocean terminating outlet glaciers produce the highest discharge rates of the Greenland ice sheet; they are all directed by descending bedrock elevations, and their mouths are associated with deep low channels carved into the bedrock (Bamber et al., 2001b). Ice streams form upstream of the ice fiords, extending far inland and with significantly increased surface velocities. The most important ocean terminating outlet glacier is the Jakobshavn Isbrae that drains into the Jakobshavn ice fiord in the west with a maximum surface velocity of about 12.6 km a^{-1} at the terminus (Joughin et al.,

Figure 3 Map of surface flow speed for winter 2005/2006 displayed over radar mosaics (©Canadian Space Agency, 2001). Reproduced from Joughin I, Smith BE, Howat IM, Scambos T, Moon T (2010) Greenland flow variability from ice-sheet-wide velocity mapping. *Journal of Glaciology* 56(197): 415–430.

2004). Another example is the north-east ice stream that drains into the 79-Fjorden in the north-east. The ice stream extends hundreds of km inland and originates near an area with high basal melt rates near the central ice divide north-west of Summit (Fahnestock et al., 2001).

Ice Deformation and Large-Scale Flow

Glacier ice flows due to gravity. In a grounded ice sheet the flow is driven by the surface slope, and glacier ice is a slowly flowing viscous material.

Large-Scale Flow Pattern

The general flow pattern of an idealized, steady-state, cross-section of the Greenland ice sheet from west to east is

illustrated in [Figure 4](#). The ice sheet accumulates snow in the high-elevation central areas (the accumulation zone), and it loses mass in the low-elevation marginal areas (the ablation zone). If the ice sheet is in steady state, the spreading of the ice sheet due to ice flow is balanced by the surface mass balance, and the shape remains constant in time. A snow particle, originally deposited at the surface in the central part, will gradually sink down and be carried with the flow to the margin. The further inland the ice is formed, the deeper it will sink before it eventually reaches the marginal areas after thousands of years and emerges at the surface, where it will be lost by surface melt or by calving of icebergs. Ice loss may also occur as basal melting and draining through subglacial tunnels, or from melting beneath floating glacier tongues. [Figure 4](#) also illustrates how an annual layer deposited near the ice divide (the central north–south running ridge that separates east flowing ice from west flowing ice) is thinned and stretched by flow as it sinks down. Ice cores are often drilled close to the ice divide, where horizontal flow is minimal, and no upstream corrections are needed.

Figure 4 General flow pattern of an idealized, two-dimensional ice sheet. The arrows indicate particle paths. The vertical line in the center is the so-called ice divide, because it separates ice flowing to the left from ice flowing to the right (similar to watershed). The horizontal lines in the center indicate annual layers (their thickness is greatly exaggerated), and illustrates how annual layers are thinned and stretched with depth. The optimal site for ice core drilling is near the ice divide, where ice movement is vertical, and no up-stream corrections are needed.

Transformation of Snow to Ice

As snow is deposited in the central areas of an ice sheet and buried by subsequent layers of snow, it is gradually transformed into glacier ice. The term *firn* is usually used to describe the material in the intermediate stages of transformation. How snow transforms into ice, and the time the transformation takes, depends on the temperature ([Cuffey and Paterson, 2010](#)). In the interior of the Greenland ice sheet, there is no melting, and the firn–ice transition depth is 65–80 m. Below the firn–ice transition, the ice density remains practically constant at 917 kg m^{-3} . Air bubbles contain samples of the past atmosphere. Due to the densification process, the age of air contained in bubbles is younger than the age of the surrounding ice.

Ice Crystals and Deformation

Glacier ice is a polycrystalline material. Below the firn–ice transition, the ice is composed of small densely packed crystals in the mm to cm size range ([Figure 5](#)). The ice crystals evolve and interact dynamically: As ice slowly descends into the ice sheet, the crystals grow and rotate, they deform and fragment, and new crystals come into existence. The average crystal size depends exponentially on the temperature of the ice, and near the bottom of the ice sheet, where temperatures generally are high, the crystals can be up to tens of cm across. The crystal size also depends on the amount of impurities in the ice. In the glacial ice with its relatively high load of impurities, the crystals are smaller than in the cleaner interglacial ice (e.g., [Cuffey and Paterson, 2010](#)).

Each crystal is built up of stacked layers of water molecules (or rather oxygen atoms), so-called basal planes. The *c*-axis is perpendicular to the basal planes and defines the orientation of the crystal ([Cuffey and Paterson, 2010](#)). It requires much less energy to deform an ice crystal in a direction parallel to the

Figure 5 The left panel shows a $10 \times 10 \text{ cm}^2$ vertical sample from a depth of 2020 m in the GRIP ice core, where the ice is about 27 ka old. As in [Figure 7](#), white layers appear where the ice has a high content of impurities (and dust). The right panel shows the same sample placed between two crossed polarizers whereby individual ice crystals become visible. Each colored field in the sample is an ice crystal, and the crystals different coloring is due to their different orientations. The impurity content and the crystal size are related, such that more impurities imply smaller crystals ([Hansen et al., 2002](#)).

basal planes than in the direction perpendicular to the basal planes. Therefore, ice primarily deforms by basal slip and the orientation of an ice crystal determines the 'hardness' of the ice with respect to deformation in a given direction. Whereas the average crystal orientation in the upper, younger part of the ice sheet is close to random, the crystals will eventually rotate and orient themselves according to the main direction of compression, so that in the deeper regions of the ice sheet, the average crystal orientation exhibit a preferred orientation. Because the average crystal orientation influences the hardness of the ice, this anisotropy of the ice plays an important role for the large-scale ice flow which must be taken into account by ice flow models.

Glacier ice deforms in a way that is intermediate between Newtonian viscous and perfectly plastic behavior (Cuffey and Paterson, 2010). The deformation is described by a flow law that relates the strain rates with the applied stresses. Laboratory experiments have shown that the deformation of glacier ice is practically independent of the hydrostatic pressure, and established a flow law in which strain rates are expressed in terms of deviatoric stresses (deviation of stresses from the hydrostatic pressure). The flow law is a nonlinear power law, where the power is usually taken to be 3. The flow law rate factor depends on many factors, most notably the temperature of the ice (increasing temperatures soften the ice), but also crystal orientation (fabric) and impurity content, as mentioned above (Cuffey and Paterson, 2010).

In all Greenland ice cores, the crystals develop a strong vertical single maximum with depth, that is, all crystal *c*-axes gradually become oriented with *z*-axes pointing vertically upward. This fabric is favorable for shear, which is the most important stress component to determine the overall flow of the grounded ice sheet, and ice sheet models have been using an enhancement factor of 3 to take this anisotropy into account (e.g., Cuffey and Paterson, 2010).

Surface Velocities

The surface velocity is normally oriented in the direction of the steepest surface slope. Surface velocities are generally low in the interior, and increasing toward the margin. Surface velocity and strain rates are measured directly from repeated observations of surface stakes by global positioning system (GPS). In the interior parts where ice movement is slow, an observation time of several years is needed in order to obtain a sufficient accuracy (e.g., Hvidberg et al., 2002). This has been done during drilling projects; otherwise, data coverage of the interior parts is sparse. Surface velocity maps are also derived from radar satellite data, and satellite radar interferometry (inSAR) has become a major tool for measuring ice motion over large areas (Joughin et al., 2010; Figure 3).

Thinning of Annual Layers with Depth

At deep drilling sites, a detailed knowledge of how flow and thinning of layers varies with depth is obtained from ice core analysis and geophysical surveys of the bore hole. The depth dependence of the horizontal velocity is measured directly only in deep bore holes. When a deep ice core is being drilled, a nonfreezing liquid in the bore hole prevents it from closing

by flow. After the drilling is terminated, the liquid-filled bore hole continues to move with the ice flow while it becomes more inclined with time. Depth variations of strain rates and horizontal flow velocities may be determined from repeated surveys of bore hole inclination. Surveys of the Dye3 bore hole in South Greenland have shown that strain rates were high in the glacial ice located in the bottom 300 m (out of a total thickness of 2000 m ice), and that the glacial ice deformed about three times faster than interglacial ice (Dahl-Jensen and Gundestrup, 1987). A simple and commonly used approximation to the depth dependence of the horizontal velocity is to assume a constant velocity down to a certain depth, and then a linear decrease to zero at the base, the so-called Dansgaard-Johnsen model (e.g., Cuffey and Paterson, 2010).

Once the ice core is dated and annual layers are identified in the ice core, timescales and vertical thinning of annual layers are known (Figure 6). Typically, the annual layer thickness decreases linearly in the upper part of the ice, and then decreases to zero at the base if there is no melting. At Summit, the ice sheet is frozen at the bed; annual layers in the GRIP ice core were 0.23 m a^{-1} of ice equivalent at the surface but decreased to fractions of a mm near the base where the ice is several hundreds of thousands of years old. At NorthGRIP, the ice is melting at the bed, with basal melt rates of 7 mm a^{-1} , and annual layers decrease from 0.20 m a^{-1} of ice equivalent at the surface to a thickness of about 7 mm a^{-1} at the base, corresponding to the basal melt rate. The basal melting at NorthGRIP has removed ice older than 123 000 years. The basal melting has prevented the basal layers from further thinning and folding, and kept the layers stratigraphically undisturbed to the bottom. It is possible to identify annual layers more than 100 ka back in time, and the NorthGRIP ice core has provided ice core records with unprecedented resolution (NorthGRIP Members, 2004).

Internal Stratigraphy

The Greenland ice sheet has built up by layers of snow deposited through tens of thousands of years. Although the ice sheet is flowing, the stratigraphic structure is preserved to great depths on both large and fine scales. The large-scale stratigraphy is known from radar soundings of internal reflecting layers, while the fine scale stratigraphy is known from ice cores. This section presents some stratigraphic data sets that are relevant for understanding the dynamics of the Greenland ice sheet.

Visible Stratigraphy in Ice Cores

Inspection of deep ice cores shows that the internal layering of ice in the glacial part of the Greenland ice sheet is clearly visible to the naked eye (Figure 7). The visible layers are caused by alternating layers of ice with variable amounts of impurities, which may consist of small dust particles or low concentrations of acids or sea salt spray. In the interglacial periods the impurity content is generally too low to be visible. In recent times, the impurities are mainly deposited during spring and summer, whereas the winter and fall snow is cleaner. Assuming a similar seasonality was active during the glacial, the visible

Figure 6 Thinning of annual layers with depth in the NorthGRIP deep ice core. The curve is based on annual layer counting and ice flow modeling (NorthGRIP Members, 2004). The annual layer thickness decreases with depth due to firn compression (only in the top 100 m) and due to flow, and reflects past variations in accumulation rate. The glacial–interglacial transition at 11 703 years b2k (Rasmussen et al., 2006) was found at a depth of about 1500 m. The abrupt shifts in annual layer thickness below 1500 m depth are due to changes in accumulation rate during the last glacial period. There is basal melting at NorthGRIP, and as a result, annual layer thickness does not decrease further below 2500 m depth.

layers in the glacial ice can be regarded as annual layers. Unlike tree rings, however, the ice core annual layers are not unambiguous because the typical ice sheet annual layer is composed of multiple precipitation events and thus contains several visible layers.

At great depths, the visible stratigraphy becomes less well defined as a result of significant thinning of annual layers. The layers become gradually blurred, and cm-scale folds emerge. Evidence of small-scale folds has been observed in several ice cores in the bottom few hundred meters (GRIP, GISP2, NorthGRIP) (Alley et al., 1997; Svensson et al., 2005). Folds are a result of local flow instabilities, thought to form due to alternating soft and hard ice, because of variations in impurity content.

Figure 7 The internal layering in the Greenland ice sheet is clearly visible to the naked eye. This shows an example of a 1.65 m-long ice core section from 1870 m depth in the NorthGRIP ice core, where the ice is about 28 ka old. The image is obtained with indirect illumination of the ice core so that black areas correspond to clear ice, whereas white layers contain visible impurities (Svensson et al., 2005).

Radar Observations of Internal Layers

Polar ice and snow is transparent to electromagnetic waves in the very high frequency (VHF) and ultra high frequency (UHF) bands, and since the early sixties, radio-echo sounding (RES) has been used to investigate the Greenland ice sheet (historical overview given by, e.g., Gogineni et al., 1998). Several data sets have been obtained in Greenland using both airborne and ground-based radars. An example of an RES image from Greenland is shown in Figure 8.

In addition to the ice surface and bedrock, RES surveys reveal internal reflection layers that can be traced over large distances. Some of the most important sources of the reflections from the internal layers are changes in density, orientation of ice crystals, and acidity (Hammer, 1980; Harrison, 1973). Many of the layers have been identified as large volcanic horizons or abrupt climate events. The layers therefore represent former depositional surfaces, and are isochrones.

The shape of the isochrones is determined by climate (especially accumulation), the amount of basal melting, and the dynamic history of the ice sheet. If the RES layers can be tracked to a deep ice core drill site, they can be dated by the timescale established for the ice core. Thus, the internal structure of the ice sheet, as it appears on RES images, contains invaluable information about the basal conditions and ice flow, and studies of internal layers may provide time scales and other information in areas where no deep core has yet been drilled. This method was, for example, used in the selection of the NorthGRIP ice core drill site (Dahl-Jensen et al., 1997).

Basal Melting

The shape of the isochrones may reveal locations with basal melting. Basal melting drags isochrones downward, because thinning of annual layers is reduced when ice is removed at the base by basal melting and draining (Dahl-Jensen et al., 1997). Ice flow models have been used together with RES data to identify locations with basal melting and to estimate the

basal melt rates in North and Central Greenland (Dahl-Jensen et al., 2003; Fahnestock et al., 2001). It is established that basal melting is widespread under the central and northern part of the Greenland ice sheet. The basal melting constitutes a significant, but not well determined part of the total mass balance of the Greenland ice sheet. The drainage system for the generated basal melt water is not well known, but the presence of liquid water at the base may play a significant role in accelerating the rate of flow of the fast-flowing ice streams. The large northeast flowing ice stream in Northeast Greenland appears to originate at a location in Central Greenland with high basal melt rates (Fahnestock et al., 2001).

History of the Greenland Ice Sheet

About 5 Ma, Northern Hemisphere ice sheets are thought to have formed as a result of a generally cooling climate (Zachos et al., 2001). Glaciers started to form in Greenland 2–3 Ma in the mountainous areas along the east coast and gradually advanced to the central plains (Souchez, 1997). Glacial and interglacial periods have since then alternated with periods of growth and decay of Northern Hemisphere ice sheets.

During the previous interglacial, the Eemian (130–110 ka BP), interpretation of the ice core isotope records suggests a warmer climate with temperatures over Greenland about 5 °C higher than at present (NorthGRIP Members, 2004). Existence of Eemian ice in all Greenland ice cores suggests that the Greenland ice sheet survived the Eemian in the northern and central part, but its extent in the southern part during the Eemian is uncertain. All deep ice cores in Greenland contain Eemian ice, including the Dye3 ice core in South Greenland, suggesting that the Greenland ice sheet was present during the Eemian. Ice sheet modeling supports that the Greenland ice sheet may have been considerably smaller during the Eemian (Cuffey and Marshall, 2000; Otto-Bliesner et al., 2006). The estimated extent and volume of the ice sheet during the Eemian depends, however, critically on the assumed temperature and accumulation rate history which is not well constrained during the previous interglacial.

At the Last Glacial Maximum, 20 ka BP, vast areas of the Northern Hemisphere were covered by ice, with large ice sheets in North America (Laurentide ice sheet), in Greenland, and in Northern Europe (Fennoscandian ice sheet). The high quality of the climate chronology archived in the Central and North Greenland ice cores indicates that the interior elevation of Greenland ice sheet and the overall flow pattern have generally been stable during the last glacial. Model simulations support the theory that a high-elevation dome was present during the glacial–interglacial cycle, and also that the divide position may have shifted with up to 150 km near Summit (Marshall and Cuffey, 2000). The suggested shifts in divide position have implied variable shear or nonshear conditions at Summit, and they could be responsible for the observed disagreements in the ice core records in the bottom 200 m of the two Summit cores, GRIP and GISP2 (NorthGRIP Members, 2004) due to folding of near-basal layers.

The transition from the last glacial to the present interglacial occurred 11 703 years b2k (Rasmussen et al., 2006). The effect on the Greenland ice sheet was complex and included a

Figure 8 RES image collected by the University of Kansas along the NNW ice ridge in Northern Greenland (Gogineni et al., 2001). The surface and the bed are indicated by the thick white lines. The internal layers are isochrones. The region of highly disturbed layers about 200 km from the summit is coincident with the suggested origin of the large northeast flowing ice stream (Fahnestock et al., 2001).

number of processes with opposite effects and with different response times up to tens of thousands of years. Increased surface-melt rates and runoff in the margin areas made the ice sheet margins retreat. At the glacial–interglacial transition, accumulation rates doubled in the central areas, and led to a build-up in the interior that has gradually spread by flow to the margin. Downward advection of warmer surface temperatures gradually softens the ice through the thermo-mechanical coupling (expressed by the temperature-dependent flow law). The evolution of the Greenland ice sheet during the present interglacial has been derived from ice core records (Vinther et al., 2009). The ice sheet has thinned by hundreds of meters at Dye3 and Camp Century that are sites near the margin, while the central areas have remained stable with little change in ice thickness. A model study considered transient effects from the last glacial to interglacial transition, on the present ice sheet, and concluded that the Greenland ice sheet is still responding to the climatic transition (Huybrechts, 1994).

Stability and Current Mass Balance

Today, the Greenland ice sheet is the largest remaining ice sheet in the Northern Hemisphere. Its stability during the present interglacial is thought to be due to a combination of high precipitation rates over Greenland, high surface elevation over the interior parts, and the surrounding coastal mountains. The proximity of the Greenland ice sheet to the Atlantic Ocean is important, because it strongly affects the climate in Greenland and provides ample supplies of precipitation. Weather systems traveling northeast across the North Atlantic carry moisture to the Greenland ice sheet. Precipitation rates in Central Greenland are of the order of tens of cm of water equivalent a^{-1} , about ten times the annual accumulation in East Antarctica (e.g., Van der Veen, 1999).

The present mass balance of the Greenland ice sheet is of particular interest because of its relation to the global sea level. The amount of water stored as ice in the Greenland ice sheet corresponds to a rise in global sea level of 6–7 m, about the same as the West Antarctic ice sheet, and the Greenland ice sheet is thought to be an important contributor to future sea-level increase.

The net mass balance is defined as the change in mass over a certain time period, and it is the result of accumulation and ablation processes. Previous estimates from before 1990 (Reeh et al., 1999) suggested that the Greenland ice sheet was close to steady state with surface accumulation of roughly 550 Gt year^{-1} , balanced equally by surface ablation and calving of ice bergs. The net mass balance was estimated by considering each term in the mass budget. However, the uncertainties were large, and data coverage was sparse.

In the last decade, several studies have reported an increasingly negative net mass balance, primarily due to a large increase of surface melt and discharge of ice, which has led to a thinning of the margin areas in Greenland (Rignot and Kanagaratnam, 2006). Repeated airborne laser altimetry surveys reported in 2000 a loss of volume of the Greenland ice sheet of about 50 Gt a^{-1} , corresponding to 0.13 mm a^{-1} , approximately 7% of the observed global sea level rise (Kravill et al., 2000). By 2003–2008, the rate of mass loss had increased to

more than 200 Gt a^{-1} , according to a compilation of satellite laser altimetry data (Sørensen et al., 2011). Some of the marginal areas are lowering with more than 1 m a^{-1} (Joughin et al., 2004) and the fast-flowing ice streams in north, west, and northeast are thinning and retreating rapidly. Over the same time period, the interior parts have been relatively stable (Johannessen et al., 2005). Gravity measurements from the GRACE satellite mission have provided the rate of mass loss from the Greenland ice sheet from 2002 to 2009 (Velicogna, 2009). During this time, the rate of mass loss has accelerated from 137 Gt a^{-1} in 2002–2003 to 286 Gt a^{-1} in 2007–2009, and the corresponding contribution to sea level rise from the Greenland ice sheet has been continuously and rapidly growing to $>0.5 \text{ mm a}^{-1}$ in 2009.

The Greenland ice sheet has been thought to respond gradually to climate changes through changes in its surface mass balance. Several new findings have challenged this view. The ice streams in north, west and northeast are associated with deep bedrock valleys, and their onset appears to be related to areas with basal melting. These glaciers drain a significant fraction of the Greenland ice sheet, but it is not yet known how changes at the margin propagate inward at the ice sheet. Recently, it was shown that near the equilibrium line in West Greenland, ice flow accelerates during periods of summer melting, and decelerates after the melting ceases (Zwally et al., 2002). This suggests a coupling between surface melting and ice flow that involves rapid migration of surface meltwater to the base and provides a mechanism for rapid large-scale dynamic response of the Greenland ice sheet to climate warming. Model simulations of the future evolution of the Greenland ice sheet and its response to a warmer climate predict increased melting and runoff in a warmer climate, but the dynamic response of the ice sheet to the changes at the margin is not yet fully understood and incorporated into ice sheet models.

Overview

Ice cores collected on highly dynamic ice sheets acquire additional complexities in interpretation; however, they return to the glaciologist additional constraints that help resolve the history of the ice sheet itself. The paleoclimatic record of such ice cores must be extracted in the context of changes in flow and shape of the ice sheet. Without knowing these changes, the paleoclimate record will contain errors.

The West Antarctic ice sheet has been intensively studied by Antarctic researchers for the past quarter century (Alley and Bindshadler, 2001). It is the type of ice sheet capable of changing suddenly and could make its demise felt worldwide by releasing enough ice to raise sea level by an average of 6 m. This might happen in centuries or longer, or perhaps not at all. The fastest changes in ice volume and sea level will be driven by changes in the flow of the ice sheet rather than changes in the rate of snow accumulating on the ice sheet or melting at the margins. Predicting such changes requires an understanding of the dynamics of this ice sheet.

Geographic and Geologic Setting

The West Antarctic ice sheet is a distinct region of the larger Antarctic ice sheet that lies predominantly in the Western Hemisphere. Its 1.9 million square kilometer area covers about 10% of the Antarctic continent. It is bounded on the south by the 3300 km long Transantarctic Mountain chain and on the north by the Weddell, Bellingshausen, Amundsen, and Ross Seas. The Antarctic Peninsula is usually not considered part of West Antarctica. West Antarctica contains the two largest ice shelves in the world: the Ross and Ronne Ice Shelves, as well as a perimeter of smaller ice shelves along the Bellingshausen and Amundsen Sea coasts (Figure 1).

The ice cradled between the Transantarctic Mountains and the coastal mountains fills a deep oceanic basin that averages more than a kilometer deep. This ocean basin includes an extensional rift basin similar to the Basin and Range region of the western United States. The thinner ocean crust leads to higher rates of geothermal heating that warm the base of the ice sheet to or near the melting point over most of the region. Warmer ice is softer and more easily deformed. Numerous volcanoes hint at a restless geology, the details of which lie mainly hidden beneath an icy mantle.

During warmer periods in Earth's past, there was little or no ice in West Antarctica and this basin was filled with a living ocean. Expired marine organisms fell to the ocean floor building up a layer of marine sediment on which the ice sheet now sits. Water, produced by the geothermal heat, weakens this marine sediment making it difficult for a thick ice sheet to find a foothold on such a soft slippery bed.

For these reasons, the West Antarctic ice sheet is thinner and more dynamic than the larger, thicker, and colder East Antarctic ice sheet. This interaction of ice, water, and sediment is the essential interplay that dictates the dynamics of the West Antarctic ice sheet. This type of ice sheet is sometimes referred to as a 'marine-based' ice sheet (Figures 2(a) and (b)).

Thin is a relative term, however, and West Antarctic ice averages over 1 km thick and in places fills the valleys of rugged subglacial mountain ranges to an overall ice depth of 2500 m. These thicknesses are more than enough to make contact with the submarine bed. As the ice flows, it becomes thinner, eventually thinning enough to float but still hundreds of meters thick. This grounded-to-floating transition occurs at the 'grounding line' and marks the beginning of a floating ice shelf. West Antarctica contains the two largest ice shelves: the Ross Ice Shelf (850 000 km²) and the Ronne Ice Shelf (257 000 km²) on either side of the West Antarctic ice sheet. These ice shelves begin with ice up to 2000 m thick at the grounding line and thin to a few hundred meters thick at the seaward perimeter of the ice sheet where tidal flexure, wind, and wave action eventually fracture the ice, releasing icebergs.

West Antarctica can be subdivided into three large regions. Identified by the receiving waters, these are the Ross Sea sector, the Amundsen/Bellingshausen Sea sector, and the Weddell Sea sector. In the Ross Sea sector, the ice is discharged via a series of ice streams, rapidly moving rivers of ice set within nearly stagnant ice ridges. These ice streams, named from south to north, Mercer, Whillans, Kamb, Bindshadler, MacAyeal, and Echelmeyer Ice Streams, are about 1 km thick, move at speeds of many hundreds of meters per year, extend for a few hundred kilometers, and are tens of kilometers wide. More elevated ice ridges of similar size lie between the ice streams, but move at speeds of less than 10 m yr⁻¹.

The Amundsen/Bellingshausen Sea sector differs from the Ross Sea sector in two significant ways. First, the ice is confined by a rim of coastal mountains through which the ice flows. The ice overrides the lower elevation peaks, creating a few rapidly moving outlet glaciers, Pine Island and Thwaites glaciers being the largest. They are similar in size to ice streams. The use of the term glacier rather than ice stream is more historical than scientific. These coastal glaciers were observed by early Antarctic explorers long before ice streams were known. The elevated terrain probably diminishes the amount of marine sediment in this area, but the subglacial setting observations are insufficient to decide how the dynamics of this region differ from that of the Ross Sea sector. The second difference with the Ross Sea sector is that the ice shelves fed by these outlet glaciers are much smaller.

The Weddell Sea sector has features somewhat intermediate to the other two sectors. It contains a large mountain range, the Ellsworth Mountains, that strongly influences the ice flow, but the major outlet features, the Rutford and Evans Ice Streams,

Figure 1 Satellite image of the West Antarctic ice sheet with various features identified. Ice streams and outlet glaciers are indicated by initials. Satellite image is a composite of data from NASA's Moderate Resolution Imaging Sensor (MODIS). Courtesy of National Snow and Ice Data Center.

resemble ice streams in form as well as name and their thick ice at the grounding line feed the large Ronne Ice Shelf.

Theories of Marine-Based Ice Sheet Collapse

The sudden demise of marine-based portions of the Laurentide and Fennoscandian ice sheets, in Canada and Scandinavia, respectively, during the last glacial period (roughly from 125 ka to 20 ka), caused episodes of rapid sea-level rise. Rates of rise exceeded 1 m per decade, more than 50 times the average rate during the twentieth century (Fairbanks, 1989). Today West Antarctica is the only marine-based ice sheet on this planet. Its modern existence poses a vexing quandary: does the West Antarctic ice sheet still exist because it is the last ice sheet of this type to suffer this inevitable fate or, conversely, may it contain some unique counterbalancing feature that causes it to avoid the fate of its Northern Hemisphere counterparts.

It has been argued that because floating ice thins faster than grounded ice of equal thickness, marine-based ice sheets may be inherently unstable (Weertman, 1974). Another argument for instability posits that ice shelves buttress the grounded ice that feeds them and any reduction of this floating portion will weaken its damming effect and lead to an increased discharge of the buttressed ice into the ocean, raising sea levels (Thomas, 1973). A deeper understanding of the dynamics of marine-based ice sheets is required to answer this disturbing question.

West Antarctic Ice-Sheet Dynamics

Ice Streams and Outlet Glaciers

The key to understanding the dynamics of the West Antarctic ice sheet is understanding the processes responsible for the observed behavior of ice streams and outlet glaciers. Nearly all the snow that falls in West Antarctica is eventually funneled through these critical features. By virtue of their speed, they are the fastest responding elements of the ice sheet and dictate whether the ice sheet grows or shrinks. In the remaining discussion, reference will be made to ice streams and not outlet glaciers. In West Antarctica, the differences are probably not significant; however, the dynamics of outlet glaciers have not received as much attention as that of ice streams.

Ice streams move fast because of the properties of the material upon which they sit and the lubrication between the ice and substrate. West Antarctic ice streams rest on marine till, a mixture of marine sediment, deposited during times when West Antarctica was open ocean, and glacial till, created by the abrasive motion of ice and encased rocks sliding across an erodable bed. The lubricating fluid is water, produced by the geothermal heat rising through the bed, and by additional friction of the ice's motion against its bed.

An ice stream's rapid motion is predominantly the result of sliding over its bed and not deformation within either the ice or the till. The weight of the ice, acting under the force of gravity, forces the ice to flow downhill. This force is counteracted primarily by resistance at the base and the sides of the ice stream (Figure 3).

Side Shear

When the bed is well lubricated (an ice shelf is the extreme case), the shearing of ice at the lateral boundaries provides resistance to flow. The work done during shearing generates heat that warms the margin, making the ice softer and prone to deform even more quickly. This is offset by the cooling effect of the slow-moving and colder ridge ice flowing across the margin into the ice stream. Modeling studies of the margin indicate they can be expected to migrate at rates of tens of meters per year (Jacobson and Raymond, 1998). Observations have confirmed that margin migration does occur in some locations at roughly these rates.

Mechanically, the resistive forces associated with side shear are transferred through the body of the slower-moving ridge to the bed. Surprisingly, specific field studies to detect differences in bed conditions across an active ice-stream margin showed no difference in water content. The tentative conclusion is that the transition from the drier bed margin to a wet till under the central ice stream is not sharp.

Basal Stress

At the ice-stream bed, water is a key ingredient. It is a lubricating fluid and its inclusion in marine till makes it extremely soft. Existing water also moves along the ice-bed interface, controlled by hydraulic pressure gradients. The pressure of this water system has been measured as being very close to the weight of the overlying ice. As the water moves, these pressures fluctuate, sometime exceeding the ice stream's weight, causing

Figure 2 Two longitudinal profiles contrasting the surface and bed shape of East and West Antarctica. The East Antarctic ice sheet is higher, thicker, and is grounded on a bed mostly above sea level. The West Antarctic ice sheet is lower, thinner, and is grounded on a bed below sea level. The East Antarctic profile begins at the South Pole and follows the 90° E longitude to the ice-sheet edge. The West Antarctic profile begins on the Ronne Ice Shelf, runs obliquely across the ice sheet, follows an ice stream, and ends at the edge of the Ross Ice Shelf.

the ice to be fully supported by the water and the basal stress to drop to zero. The surface topography influences the subglacial hydrology more than the basal topography, but both are relevant, so the pattern of subglacial water flow can be different from the ice-flow pattern and changes in the surface can alter the flow patterns of ice and water differently.

As with the sides, heat flow is a critical factor in determining the influence of the bed on ice flow. An excess amount of heat can melt basal ice and keep the bed lubricated, whereas a heat deficit will cause water to freeze, removing the lubricating fluid, drying the till, and making it stiffer.

There is lingering controversy as to how much the deformation of the till contributes to ice-stream motion (Kamb, 2001). A till in front of active ice streams shows foresetted beds that indicate downstream transport and redeposition of till (Alley et al., 1989). In addition, ice penetrating radar measurements of the bed beneath active ice streams show long furrows in the till aligned with the flow direction, suggesting the active sculpting of the till by the ice stream. There is

probably an active layer of very deformable till immediately beneath the ice stream. The depth of this active layer depends on the thermal and hydrologic conditions and as these factors change, so will the characteristics of the active layer (Figure 4).

Transitions and Tributaries

At the ends of an ice stream, a third resistive force becomes important. When the ice stream enters the ice shelf, basal resistance is lost and the nearby margins are replaced by margins much farther away. These sudden changes would cause a dramatic jump in speed, were it not for longitudinal stress acting along the direction of motion smoothing this transition. Another transition occurs at the upstream end where ice streams start. This transition is also gradual and takes place within well defined geologic troughs that allow thicker ice to accelerate. The accelerating ice defines 'tributaries' that coalesce into larger, faster flows (Joughin et al., 1999). The tributaries can extend a few hundred kilometers upstream of the ice stream's origin, or

Figure 3 Mosaic of Landsat images and color map of surface velocity of Bindschadler (right) and MacAyeal (left) Ice Streams. Flow is from top to bottom and velocities range from near zero (blue) to 700 m yr^{-1} (purple). Central portion of each ice stream flows fastest. Slower ice at the margins is wider on Bindschadler Ice Stream. Data coverage of surface velocity is not continuous over Ross Ice Shelf, toward bottom of figure, where two ice streams merge. Black bar at top represents a distance of 100 km.

Figure 5 Pattern of West Antarctic ice surface speed shows the network of tributaries feeding ice streams and outlet glaciers. Slowest speeds are in brown, then yellow, with fastest speeds of over 500 m yr^{-1} in magenta. Colors are superimposed on radar mosaic of West Antarctica. Image courtesy of I. Joughin.

‘onset’. Basal sliding is likewise the dominant process of ice motion. When ice speeds reach about 100 m yr^{-1} , increased side-shear stresses begin to form crevasses (Bindschadler et al., 2001). The positions of onsets may be dictated by the presence of the marine till because they closely match the paleoshoreline of an ice-free West Antarctic after accounting for the full recovery of the earth’s crust following removal of the ice load (Blankenship et al., 2001). Alternatively, the gradual increase in basal heat, caused by increased sliding, may determine when the supply of subglacial water is sufficient to sustain an ice stream’s rapid motion. The ice streams exhibit a generally straighter flow direction and are steered less by the subglacial topography than the tributaries that feed the ice streams. The paths of ice streams sometime disregard the topography altogether, occupying one side of a deep subglacial valley and not the other side, or straddling a portion of a valley and the surrounding elevated terrain. This reinforces the fact that the margins of ice streams can migrate (Figure 5).

Important Timescales

One of the most confusing aspects of West Antarctic ice-sheet behavior is that change has been observed on many different timescales. This can confound scientific study and make comparison of data difficult.

Glacial Timescale

Over the past million years, Earth has experienced waxing and waning ice sheets at a general 100 ka periodicity: glacials

Figure 6 Bathymetry of the Ross Sea shows sequence of ridges (red) and troughs (yellow) trending north–northeast. Troughs were occupied by paleo-ice streams of a former, larger West Antarctic ice sheet. Map courtesy of J. Anderson.

lasting about 90 ka separated by interglacial periods typically lasting 10 ka. The West Antarctic ice sheet is known to have been largely absent at least once during the last 400 ka based on ocean-dwelling diatoms found in subglacial sediments recovered from beneath the center of the ice sheet (Scherer, 1991). It has not been successfully determined whether the West Antarctic ice sheet survived the last interglacial (that peaked about 125 ka). If not, it underscores the importance of the question of why this ice sheet persists when the present interglacial has lasted twice as long as the average.

It is easier to map the extent of ice sheets during their more extensive glacial periods because the postglacial retreat reveals the former subglacial beds and margins. The deep-carved troughs that stretch to nearly the edge of the continental shelf around West Antarctica confirm both the former extent of the ice sheet and the former existence of ice streams. Ice covering the Ross Sea began its retreat about 11.400 ka, later than the retreat initiation 18 ka in the Northern Hemisphere and in parts of East Antarctica. Portions of the retreat were rapid, with a retreat hiatus occurring about 7 ka when the front was in the vicinity of Ross Island (Conway et al., 1999). This hiatus may be associated with a widespread mid-Holocene warm period evidenced throughout much of Antarctica.

Thinning, associated with this retreat, has been followed in the near-coastal Ford Ranges. The time when previously ice-covered rocks are first exposed can be determined by measuring the decay rate of certain chemical isotopes. The highest summits emerged about 10.4 ka and the lower summits as recently as 3.8 ka. Thinning is presently continuing. Average exposure time of the Ford Range summits over the more distant past is less than 50% while the lower elevations that are most recently exposed have been exposed less than 1–5% of the time. This means that the ice extent in this region is at an extreme minimum and probably less than during the extended and very warm interglacial 400 ka.

More interior sites experienced lesser amounts of thinning. Isotopic analysis of ice cored from Byrd Station indicates it was no more than 400 m higher during the Last Glacial Maximum (Steig et al., 2001). Reedy Glacier, at the very southern extreme of West Antarctica, too was only a few hundred meters higher and experienced a more gradual drawdown during the past 10 ka. Internal layering revealed by ice-penetrating radar and dated by an ice core has been used to deduce that Siple Dome was likely overrun by the glacial ice sheet, did not begin to thin until 7 ka, and emerged as an ice dome about 3 ka, supporting the theory of unsteady retreat (Figure 6; Nereson and Raymond, 2001).

Millennial Timescale

Not only is the size of the West Antarctic ice sheet ephemeral, the ice streams within it are short-lived as well. The fast motion of active ice streams creates crevassed margins and rough surfaces. Past margins have been identified by ice-penetrating radars and can be seen in satellite imagery. The region of slow-moving ice between Whillans Ice Stream and Mercer Ice Stream is now relatively slow moving, but its rough surface and buried crevasses suggest it flowed at ice-stream speeds sometime in the past.

Distinct paleomargins identify and define a former ice stream, unofficially dubbed ‘Siple Ice Stream’, that flowed northwesterly across the upstream side of Siple Dome. It was active until about 450 yr ago and may have directed the upstream region of Kamb Ice Stream into the downstream region of Bindshadler Ice Stream (Gades et al., 2000).

Some former margins are so clearly defined it is unreasonable to expect that they migrated gradually to their present positions. Thus, the dynamics of ice streams must include provision for margins to jump distances of many kilometers. It is not known how suddenly this would occur and whether a

brief period of inactivity would be required. The self-sustaining aspect of streaming flow, the possible difficulties of restarting a stagnant ice stream, and the observation that near an active margin the subglacial till underneath the ice stream is relatively dry, make it likely that margins can at least jump inward without needing to stop streaming flow.

Surface ridges and troughs that stretch along the length of fast-moving ice streams tracing out the direction of flow aid in disclosing past changes in flow direction. Called 'flowstripes', 'flow traces', or 'streaklines', these features are created by irregularities of either basal topography or basal lubrication. Similar to medial moraines on mountain glaciers, these features align with the velocity field when flow is steady for long periods of time. Misalignment indicates nonsteady flow.

Flowstripes being transported across the large Ross and Ronne ice shelves provide a means to look back at the flow pattern emanating from the grounded ice streams for the past few centuries. Ice presently near the seaward edge of the Ross Ice Shelf entered the ice shelf about 1 ka. Large bowed structures are indisputable evidence of major changes in flow having occurred in the region now fed by the Whillans and Mercer Ice Streams. The analysis of this large bowed pattern, other less emphatic flowstripe deviations, and crevassing patterns indicate that there were some major flow changes in the West Antarctic ice streams feeding the Ross Ice Shelf about 500 yr ago (Fahnestock et al., 2000). By contrast, the flowstripes discharged from the East Antarctic ice sheet, through the Transantarctic Mountains into the Ross Ice Shelf and the general pattern across the Ronne Ice Shelf align well with present flow, indicating steady flow direction (Figure 7).

Figure 7 Satellite image of a portion of the Ross Ice Shelf shows bowed flowstripes indicating a large change in flow occurred upstream in the past. Transantarctic Mountains are in the upper right and ice flow is from upper left to lower right. As ice flows around Crary Ice Rise (grounded ice in the mouth of Whillans Ice Stream indicated by the bright and dark feature left of center), crevasses are formed that are carried along the ice shelf.

Centennial Timescale

The most recent known stagnation event of the West Antarctic ice sheet took place on Kamb Ice Stream. The amount of snow covering its once active ice margins indicates it stopped suddenly over most of its length approximately 150 yr ago (Smith et al., 2002). The tributary system feeding the ice stream remains active, forming a bulge of ice growing at about half a meter per year and unable to exit the ice sheet. How the growth of this bulge will evolve and whether the lower ice stream will reinitiate, are ongoing research questions motivating sustained field observations.

There has also been speculation about what caused the stagnation. The present geometry is diverting subglacial water from flowing underneath Kamb Ice Stream to flowing south into the still-active Whillans Ice Stream. One theory claims that this diversion caused stagnation of Kamb Ice Stream. Another theory disputes this, contending that the hydrologic diversion was a consequence, rather than a cause, of the stagnation and that the ice stream thinned enough to freeze basal water, stiffen the till, and stop the stream, forcing upstream water to go elsewhere (Anandakrishnan et al., 2001).

Decadal

Field studies of the flow of the West Antarctic ice sheet began in the early 1980s and satellite data extend to the early 1960s, allowing direct measurements of change on the decadal timescale. Acceleration, deceleration, and steady flow are all observed. Curiously, these three different regimes occur distinctly in the three different geographical regions of West Antarctica. Acceleration is most commonly observed in the Amundsen Sea region. Pine Island and Thwaites Glaciers and some of the much smaller outlet glaciers are accelerating at rates of a few percent per year (Rignot and Schmelz, 2002). These rates cannot have been sustained for decades without there being many far-ranging and observable changes elsewhere. Thus, they are likely a recent occurrence.

There has been a decrease in the velocities across the entire Whillans Ice Stream at the typical rate of $1\text{--}2\%$ yr^{-1} since the 1980s (Joughin et al., 2002). Slightly higher rates have been observed downstream where basal freezing is likely, implying that the removal of water is making the till stiffer, increasing the basal resistance to flow. It is possible this deceleration will eventually result in stagnation of the ice stream.

In the Weddell Sea region, no sustained changes in flow speed have been observed over this same multidecadal period.

Twenty-five years of surface elevation measurements by satellite altimeters show a pattern of change consistent with the spatial pattern of velocity change: the Amundsen Sea sector is thinning; the Ross Sea sector is thickening; and the Weddell Sea sector is roughly in equilibrium (Wingham et al., 1998). The thickening in the Ross Sea sector is primarily the result of the stagnant Kamb Ice Stream. Based on the most recent laser altimetry results, the decelerating Whillans Ice Stream is now contributing to this thickening, while the other active ice streams are thinning slightly. In the Amundsen Sea sector, there are major changes taking place in many of the outlet glaciers (discussed below). However, Thwaites Glacier stands out as a major outlet whose current flow is considerably

different from what accumulation and geometry suggest should be the discharge pattern of this glacier.

Daily

Ocean tides have a surprisingly large effect on ice stream motion. Precise Global Positioning System (GPS) positions indicate that where ice streams enter both the Ronne and Ross Ice Shelves, ice flows about 10% faster during periods of intense tides. In the Ross Sea sector, there is even more dramatic sensitivity: most of the lower ice streams accelerate to flow 50% above their mean speed during falling tides with a symmetric deceleration to speeds approximately 50% below the average during rising tides (Anandakrishnan et al., 2003). The notable exception is Whillans Ice Stream which exhibits stick-slip motion: most of the motion occurs during two brief episodes lasting 20–30 min during falling tide. During these slip events, speed corresponds to that expected for a completely lubricated bed and the acceleration and deceleration require no more than one to a few minutes (Bindschadler et al., 2003). In all cases of tidal modulation, the phenomenon decays gradually upstream, but can still be detected more than 100 km from the grounding line.

The timing of the stick-slip events can be reproduced by a simple, plastic-bed model where the slip occurs after a threshold strain is exceeded. It is probably important that the only ice stream exhibiting stick-slip is also the ice stream experiencing strong basal freezing of basal water. It is unlikely that the tidal variations actually transport water significant distances under the ice. The tidal effects are probably transmitted either via pressure through the subglacial hydraulic system or by longitudinal stresses within the ice. A more complex model is needed to explain the gradational response of the other ice streams.

A View of the Future

Satellite sensors have revealed the multiple facets of a rapidly shrinking ice sheet in the Amundsen Sea region where Pine Island and Thwaites glaciers are the major outlets. Both they and their neighboring glaciers are accelerating and thinning most rapidly nearest the coast (Shepherd et al., 2004). This is the pattern expected of an ice-sheet collapse. Recent airborne observations establish that thinning is accelerating (Thomas et al., 2004). The consistent and widespread pattern suggests external forcing. Nearly none of the former ice shelf remains and the extent of the fringing sea-ice cover is decreasing, as well. These factors may be significant because the larger magnitude changes at the coast suggest that they are at least partly driven by the influx of warmer waters up onto the continental shelf, where currents lead them to interact with the underside of the ice shelf and other floating ice (Figure 8).

Extensive warming on the Antarctic Peninsula has led to the sudden disintegration of individual ice shelves along both east and west coasts, driven by intense summer melting. In one monitored case, ice upstream of a removed ice shelf accelerated in agreement with the theory contending that the grounded portion of the West Antarctic ice sheet is buttressed by the ice shelf and that removal or thinning of the shelf will lead to acceleration and thinning of the grounded ice (Scambos et al., 2000). The present Amundsen Sea behavior also conforms to this pattern. Presently, the Ross and Ronne Ice Shelves have experienced only occasional summer melting. Many more degrees of warming will be required to increase the frequency and the intensity of summer melting on these ice shelves.

Research on the dynamics of the West Antarctic ice sheet is intended to produce knowledge of the important processes so that predictions of the future behavior of the ice sheet can be

Figure 8 Composite figure showing elevation changes taking place in West Antarctica. Results are processed from satellite radar altimeter data. Figure courtesy of H.J. Zwally.

made well in advance of dramatic change to the ice sheet and global sea level. Numerical models are the tools to make these predictions of the future. Models of the West Antarctic ice sheet with variable grids can include adequate resolution to capture the important features but they do not yet include all the complex interactions between ice, till, and water in ways that reproduce the observed and inferred behavior on the variety of timescales known from observations. Recent models have been able to simulate ice-stream stagnation and reactivation through thermal triggering and are also becoming better at matching the variety of field data of motion, flow history, and temperature structure (Hulbe and Payne, 2001). The compelling importance of knowing the heat budget requires these models to be fully thermodynamic. Also, the fundamental nature of water in a variety of ways also requires calculation of not only water balance, but also subglacial water flow, and its effect on till strength. These are challenges that will be met as knowledge of the dynamics of the West Antarctic ice sheet improves.

The Antarctic Ice Sheet ([Figure 1](#)), Earth's largest glacier, forms the highest-elevation continental surface on Earth. The East Antarctic portion of this ice sheet is located primarily in the eastern hemisphere between longitudes 30° W and 165° E; it flows into and is contiguous with the smaller and lower-elevation West Antarctic Ice Sheet, which is located primarily in the western hemisphere. These two components of the ice sheet are largely dynamically independent, because they are separated by the Transantarctic Mountains. The West Antarctic Ice Sheet is a 'marine ice sheet', grounded well below sea level. (See the article on [Dynamics of the West Antarctic Ice Sheet](#) by Robert Bindshadler in this encyclopedia.) By contrast, the much larger East Antarctic Ice Sheet is grounded on continental crust that is mostly, although not entirely, above sea level.

The East Antarctic Ice Sheet reaches elevations exceeding 4000 m above sea level at Dome Argus near its center ([Figure 2a](#)), has an area of 9 855 570 km², an estimated volume of 25 920 000 km³, a mean thickness of ca. 2630 m, and a maximum thickness of 4780 m ([Drewry, 1983](#)). The ice sheet rests on continental crust ([Figure 3](#)) that includes large subglacial basins and several mountain ranges, some of which are entirely subglacial. Some regions of the bed are below sea level, because the weight of the ice sheet has caused depression of the lithosphere, forcing viscous rock in the asthenosphere to flow out from beneath the ice load. [Figure 4](#) shows the distribution of ice thickness. Many of the details of ice flow remain unknown, but satellite remote sensing is yielding steadily-increasing information (e.g., [Bamber et al. \(2000\)](#)). Here, we describe some general features of the flow field of the ice sheet that can be inferred from glaciological principles.

The East Antarctic Ice Sheet, like all glaciers, flows in response to gravity. 'Ice-sheet dynamics' refers to the ways in which the ice sheet deforms, flows, and changes through time in response to changes in accumulation associated with changing climate, to changes in ocean temperatures, and to changes in relative sea-level at the margins and grounding lines. In a depth-averaged sense, ice flows down the surface slopes, from higher to lower surface elevations. Thus, to a good approximation, a map of ice-flow directions can be made from a surface elevation map because the ice flows at 90 degrees to the elevation contours.

At any given depth in an ice sheet, the ice above flows faster than the ice below. This vertical gradient in the flow velocity causes shear deformation ([Figure 5a](#)). The magnitude of this shear deformation is maximum at and immediately above the bed, and decreases with height above the bed. The flow velocity thus increases most rapidly immediately above the bed. It increases more slowly at greater heights above the bed, reaching a maximum at the surface. Like other viscous fluids, glacier ice flows faster when its surface slope is steeper, and when its thickness is greater.

The constitutive properties or 'stiffness' of ice are described by a flow law, which quantifies the relationship between deformation rates and the stress field in three dimensions. This relationship is strongly nonlinear; ice sheets are modeled as power-law fluids. The flow law of ice is also strongly temperature-dependent; ice is softer and thus deforms more rapidly at higher temperatures.

Ice sheets can also slide over their substrates if the basal ice is at the pressure-melting temperature and if sufficient water is present, from basal melting, to lubricate the interface. If the substrate is relatively smooth and soft; for instance, water-saturated subglacial till or mud, or a subglacial lake, then basal motion can be enhanced further. [Figure 5b](#) shows typical trajectories followed by ice particles in a vertical section as they flow from the ice-sheet interior toward the coast. Hooke (2004) and [Paterson \(1994\)](#) offer in-depth mathematical and theoretical treatments of both ice deformation and basal motion.

The ice sheet is formed from precipitated snow. The snow compacts to form glacial ice over time scales of hundreds of years, due to the overlying weight of accumulating snow. East Antarctica is a climate desert; the net accumulation of snow, expressed as ice-equivalent thickness, is less than 10 cm annually over large areas ([Figure 6](#)). On the steeper slopes near the coast, orographic lifting of maritime air leads to higher precipitation rates. A year or more can pass without snowfall in the driest regions. Much snow is drifted by the wind and some is blown from the ice sheet. The small amounts of snow that fall are largely preserved, because low air temperatures, even in summer, preclude melting on the surface of the East Antarctic Ice Sheet, with the exception of some small regions near the margins. [Figure 7](#) shows the mean annual surface temperatures on the ice sheet. In Antarctica, as elsewhere, Earth's crust is heated by decay of radioactive elements. This geothermal energy from the solid Earth must ultimately be conducted upward through the ice, from the warm rock toward the colder atmosphere, and this heat transfer requires a temperature gradient. This geothermal gradient causes temperatures to be much warmer at the base of the ice sheet than at its upper surface. Additional heat can be generated by shear deformation rates within the ice. Shear deformation rate is generally greatest in the basal ice ([Figure 5a](#)). The basal ice is warmer and is therefore softer than the ice above; this can further enhance shear deformation in the basal ice. If the combination of geothermal energy and deformational heat causes the basal ice to reach the pressure-melting temperature, this can, in turn, lead to sliding, or to basal motion through deformation of a soft water-saturated substrate. The frictional heat of basal motion can in turn generate more melting, further enhancing basal motion. The highest rates of basal melting occur beneath the Antarctic ice shelves, which are floating seaward extensions

Figure 1 The East Antarctic Ice Sheet covers the area between longitudes 165°E and 30°W and is bounded by the Southern Ocean and the Transantarctic Mountains. Byrd Glacier, Lambert Glacier, Slessor Glacier, and Foundation Ice Stream are examples of major outlet glaciers. Ross, Amery, and Ronne-Filchner are the major ice shelves. DML (Kohnen Station, Dronning Maud Land), Dome Fuji Station, Vostok, and Dome C are sites of deep ice cores. (Antarctic image from Radar Antarctic Mapping Program (RAMP), courtesy of Alaska Satellite Facility.)

of the grounded ice sheet, where the oceanic heat flux can be much higher than the geothermal flux.

The East Antarctic Ice Sheet has been present for ca. 40 Myr; however, ice continually cycles through the ice sheet on much shorter time scales. As illustrated in [Figure 5b](#), ice accumulates in the high interior, flows toward the margins, and leaves the continent as icebergs, which calve from coastal glaciers or from ice shelves. Over time, the ice sheet has adjusted its shape to establish a near-equilibrium state, in which its thickness, slope, and internal and basal temperatures combine to cause basal motion and flow by internal deformation that can transport, in an average year, just the correct amount of ice to balance the total amount of accumulation that falls upstream in an average year. Glaciologists often define a flow band as the portion of the ice sheet bounded by a pair of flow lines on the surface, as shown in [Figure 2b](#). Ice is unlikely to cross through the vertical surfaces beneath each flow line. In three dimensions (3-D) ([Figure 8](#)), ice accumulates on the upper surface of the flow band by snowfall, and ice flow carries ice through the vertical section between the two flow lines. This vertical surface can be called a “gate”. In a steady state, the volume of ice transported through the gate in 1 yr is equal to the volume of ice accumulated upstream on the flow-band surface in 1 yr. The average velocity of ice passing through the gate is called the balance velocity U . Because the largest velocities are generally found at

the surface ([Figure 5a](#)), the balance velocity is smaller than the actual ice velocity that would be measured at the ice-sheet surface; however, their relationship can be estimated using ice-flow theory to estimate the contribution of basal motion, and the rates of internal deformation (see [Hooke \(2005\)](#) and [Paterson \(1994\)](#)). [Figure 9](#) shows the balance-velocity distribution on the ice sheet. Although we have very little information on the actual velocities due to internal deformation and sliding in East Antarctica, the balance velocity can generally be used as a good approximation to their depth-averaged sum. Clearly, the flow is slow in the interior, but speeds up dramatically as ice is funneled into a few major outlet glaciers such as Byrd Glacier ([Figure 1](#)) where the ice flows rapidly through gaps in the Transantarctic Mountains. Even where the ice sheet abuts the Southern Ocean, flow is concentrated into a few large fast outlet glaciers, because fast flow causes erosion of deep bedrock troughs, and these troughs in turn encourage faster flow. Some ice is also discharged through ice streams, which are fast-flowing currents within the more sluggish mass of the surrounding ice sheet. Foundation Ice Stream ([Figure 1](#)) is one example.

The dynamics of the ice sheet also control both the distribution of age within the ice, and the increasing degree of vertical thinning and horizontal stretching that layers of ice have experienced by the time that they arrive at each depth, at

Figure 2 (a) Surface topography of Antarctica, in meters. The East Antarctic Ice Sheet reaches an elevation greater than 4000 m at Dome A. (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.) (b) Flow lines (black) from the interior to the coast are approximated by steepest-descent paths, at 90° to the elevation contours (blue). Most of the ice discharge from East Antarctica is funneled into fast-moving outlet glaciers. (Figure courtesy of I. Joughin.)

each location on the ice sheet. It is possible to estimate the age distribution with depth that might be expected in an ice sheet, following a simple thought experiment. First, imagine building up an ice sheet to thickness H from nothing, by depositing successive layers of ice with thickness b , one layer each year. Furthermore imagine that these layers do not flow or deform.

As **Figure 10a** illustrates, the time to build the ice sheet is then $\tau = H/b$. For central East Antarctica, H is ca. 3 km, and b is ca. 0.05 m yr^{-1} or less when averaged over 100-ka Ice Age cycles. Under these conditions, this characteristic time τ is ca. 60 ka.

Because the ice sheet is actually flowing, and because the speed increases with distance from an ice divide, stretching

Figure 3 Bed topography under the Antarctic ice sheets, in meters above sea level. While several large basins are currently below sea level, peaks of the Gambertsev Subglacial Mountains below Dome A (Figure 1) approach 3 km above sea level. (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.)

Figure 4 Ice thickness map, (ice thickness in meters). The most extensive areas of very thick ice (in excess of 4 km) are found west of Dome C (Figure 1). (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.)

layers along the direction of flow, a layer gets progressively thinner with time (Figure 10b), and typically an order of magnitude more layers can be stacked into the depth H , suggesting that ice cores should recover 600-ka climate records. Cores from Vostok, Dome C, Dome Fuji Station, and Dronning Maud Land (Figure 1) all recovered climate records going back on the order of a half million years, confirming the validity of this simple estimate based on ice dynamics.

Because of its extreme cold climate and limited melting, the East Antarctic Ice Sheet has been more stable than other Earth's other ice sheets. Ice sheets can lose mass rapidly if accelerated

flow of ice streams and outlet glaciers significantly exceeds upstream accumulation. This dynamical thinning can draw down the inland ice much faster than passive melting alone could achieve. This appears to be the way that former ice sheets have disappeared during times of warming climate. Ice shelves and floating glacier tongues seaward of outlet-glacier grounding lines appear to provide a buttressing restraint. They also protect the fronts of those glaciers from warm seawater. Acceleration of some outlet glaciers appears to be initiated primarily by thinning and breakup of such ice shelves and floating glacier tongues (Scambos et al., 2000). In many outlet glaciers,

Figure 5 (a) Pattern variation of ice-flow velocity with depth in the East Antarctic Ice Sheet. The ice may slide along the basal substrate (bedrock or soft sediments) as indicated by u_b . Ice also experiences internal deformation or shearing flow, in which the ice above any level flows faster than the ice below; the rate of shearing is greater at greater depths. Because the ice sheet is close to a steady state, the ice at the surface at any site also moves downward at a rate that balances the annual accumulation rate b . The downward velocity diminishes with depth; at the bed, the bed-convergent motion just balances the basal melting rate, which typically varies between zero and a few millimeters annually. (b) Flow pattern along a typical flow line from the ice sheet interior to the coast. Where the water depth exceeds 9/10 of the ice thickness, the ice floats and is called an ice shelf.

Figure 6 Accumulation map (accumulation rate (ice equivalent) in units of mm per year). The interior of East Antarctica is a desert. (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.)

fast flow is due primarily to fast basal motion. Ice discharge through these glaciers can increase rapidly if faster flow then produces more water at the bed. Because of this positive feedback, outlet glaciers control the future of ice sheets.

Some ice shelves have been lost on the Antarctic Peninsula in recent decades (e.g. Scambos et al., 2000). Some outlet glaciers on the Greenland Ice Sheet and the West Antarctic Ice Sheet (see Bindshadler, *this Encyclopedia*) are currently undergoing dramatic accelerations in response to warming climate. Although the East Antarctic Ice Sheet today appears to be close to steady-state, it also has buttressing ice shelves, large fast outlet glaciers, and large areas where the bed is below sea level. If increased basal melting of ice shelves, for example due to increasing temperatures in the Southern Ocean, were to cause thinning and breakup of the ice shelves, the resulting reduction of buttressing effect could cause acceleration of the ice streams

and outlet glaciers that feed the ice shelves. These processes, if they were to occur, could cause dynamic thinning of the inland ice sheet when ice discharge exceeded replacement by accumulation. The East Antarctic Ice Sheet too could respond rapidly to climate change, if its ice shelves should fail in a warmer world.

Future measurements promise to produce a more-detailed picture of the dynamics of the East Antarctic Ice Sheet. Satellite remote sensing using interferometric Synthetic Aperture Radar (inSAR) is producing progressively better maps of ice-flow velocities at the surface. Satellite altimeters (both laser and radar) are revealing transient flow and vertical motions related to changes in the accumulation pattern (climate), and to changes in basal conditions such as transient water storage (e.g. Wingham et al., 2006). Subtle changes in the gravitational field over Antarctica based on orbits of tandem satellites such

Figure 7 Mean annual temperature at the ice-sheet surface (in °C). The interior of East Antarctica is the coldest region on Earth. (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.)

Figure 8 When a gate is defined as a vertical section between two flow lines on the ice-sheet surface, and transverse to the ice flow, the balance velocity U is the velocity needed to carry a volume of ice through that gate in 1 yr that is equal to the volume of ice accumulating upstream from the gate and between those two flow lines in 1 yr.

Figure 9 Balance-velocity map (in m per year). Ice in the interior flows slowly, but as it approaches the coast it is funneled into fast-moving outlet glaciers such as Byrd Glacier, Lambert Glacier, Slessor Glacier, and Foundation Ice Stream (see Figure 1). (Figure courtesy of J. Kallen-Brown. Data set courtesy of D. Vaughan.)

Figure 10 (a) By considering how many years it would take to build an ice sheet of thickness H by stacking up the annual accumulation b in the absence of flow, a characteristic time scale $\tau = H/b$ for growth of a polar ice sheet can be derived. (b) Real ice sheets flow, and the layers are stretched and thinned as they get older. The same time scale $\tau = H/b$ is characteristic of ice deformation, giving a rough estimate of the time required for a layer to thin by 50%. An ice core can be expected to recover a paleoclimate record spanning approximately 10τ .

as the GRACE mission (Wahr et al., 2000) can detect changes in ice mass; however the short temporal baseline and ongoing isostatic rebound are complications still being resolved. Future measurements in the ice sheet itself will also improve knowledge and understanding of the ice dynamics. For example, there is considerable interest in development of a coiled-tubing hydraulically-driven drill system to make low-cost access holes. Holes could be drilled in a few days, and kept open indefinitely with appropriate environmentally friendly, low-density anti-freeze fluids. Such holes would permit measurements of geothermal flux and temperature distribution within the ice sheet, and direct measurements of the pattern of internal deformation and sliding (Figure 5a). By offering direct access to the subglacial bed, holes would also permit measurements of the properties of subglacial materials that control the dynamics of basal motion.

History of Carbon Monoxide and Ultra-Trace Gases from Ice Cores

M Aydin, University of California, Irvine, CA, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

Air trapped in polar ice cores has proven to be a valuable archive for determining paleoatmospheric levels of trace gases such as carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (NO₂). The ultra-trace gases (e.g., carbon monoxide, nonmethane hydrocarbons, carbonyl sulfide, methyl chloride) have weaker emissions and are removed faster from the atmosphere, resulting in abundances as low as a few parts per trillion (ppt) in the most extreme cases. Despite very low atmospheric abundances, ultra-trace gases have a profound influence on the chemistry of the atmosphere and impact global climate, drawing interest from a wide range of scientific disciplines. The ambient mixing ratios of many ultra-trace gases are routinely measured as part of atmospheric sampling networks (e.g., <http://www.esrl.noaa.gov/gmd>). Establishing the past atmospheric variability of ultra-trace gases will contribute to our understanding of the feedback mechanisms between the global biogeochemical systems and the climate, as well as providing opportunities to observe past variability in the chemistry of the atmosphere.

Ice core ultra-trace gas measurements present many analytical challenges. Ice cores contain only ~10% air by volume. Using large amounts of ice is not feasible because of both practical limitations on extraction techniques and the fact that these procedures require destructive sampling of rare and valuable ice cores. In most cases, ice core gas analyses are carried out with considerably smaller samples than typically used in atmospheric measurements. As a result, even minor levels of contamination can present significant problems and lead to experimental artifacts. Contaminants can be introduced during drilling, transport, storage, sampling, extraction, and analysis phases. Implementing clean handling procedures and using the right materials for the application throughout these phases are often the most critical components in ultra-trace gas measurements.

Potential causes of measurement artifacts are not limited to external contaminants. Chemically reactive gases can be produced or lost while still in the snow, in the firn before getting trapped in ice cores, or within the ice core matrix. Such *in situ* effects can be very difficult to identify. Direct verification of the ice core measurements with contemporaneous real-time atmospheric data can be difficult to achieve. Shallow ice cores from high accumulation rate sites contain air from the second half of the twentieth century and represent the only means for direct verification of ice core measurements. Often, confirming the fidelity of the ice core ultra-trace gas records requires an indirect approach, in which determining the atmospheric composition of the recent past through analysis of firn air plays a crucial role. Firn air gas records can overlap with both the real-time atmospheric measurements and the youngest (most recent) time periods that can be studied with the ice core records. Ultimate confirmation requires agreement between multiple firn air and ice core records.

So far, only a handful of ultra-trace gases have been successfully measured in ice cores. The following sections include a review of the published literature on ice core measurements of four such ultra-trace gases: carbon monoxide, carbonyl sulfide, methyl chloride, and methyl bromide. The research is still in its preliminary stages. In this context, successful measurements refer primarily to confidence in the analytical procedures and the data thus generated. Much progress is needed on the verification front. There is reasonably good evidence that the data presented in this chapter represent the true composition of the past atmosphere; however, this issue is an open question and will remain so until the existing records can be reliably reproduced with measurements from multiple ice cores.

Carbon Monoxide

Carbon monoxide (CO) is one the most important ultra-trace gases in the atmosphere. It is readily removed from the atmosphere via oxidation with the hydroxyl radical (OH) and is considered a short-lived gas. OH is the most important oxidant in the atmosphere and CO oxidation is the primary removal mechanism for it. The oxidation chemistry of CO also affects other atmospheric oxidants such as ozone (O₃) and hydroperoxy radical (HO₂). Consequently, atmospheric CO levels have considerable influence on the overall oxidative capacity of the atmosphere and indirectly impact the abundance of most trace and ultra-trace gases (Bakwin et al., 1994; Novelli et al., 1998).

CO is emitted from a variety of anthropogenic and natural sources, which include fossil fuel combustion, oxidation of methane and nonmethane hydrocarbons, biomass burning and biofuel use, and to a lesser degree, plants and oceans (Duncan et al., 2007; Khalil and Rasmussen, 1988, 1990). Anthropogenic emissions, which comprise more than half of the total CO emissions today, occur mostly in the northern hemisphere. The uneven distribution of sources coupled with a short lifetime results in large interhemispheric gradients. At the end of the twentieth century, the annual mean CO mixing ratios in the high latitudes of the northern and southern hemispheres were ~120 and ~50 ppb, respectively (Novelli et al., 1998, 2003). In the absence of anthropogenic emissions, source-driven variations in atmospheric CO levels would likely be due to changes in biomass burning emissions and atmospheric CH₄ levels. Any change in the oxidative capacity of the atmosphere would also impact the abundance of CO in the preindustrial atmosphere.

CO has been measured successfully in polar firn air from Berkner Island, Antarctica (Figure 1). The top 40 m of the firn column at Berkner Island is impacted by seasonal CO variability at the surface. Below 40 m, the CO levels drop from ~52 ppbv (parts per billion by volume) at 50 m to ~46 ppbv at 59 m. It is necessary to use a firn air model to develop an atmospheric history based on these measurements. Based on the modeling results, the Berkner Island data imply that the CO levels over

Antarctica were likely lower than 40 ppbv at the beginning of the twentieth century and rose to above 50 ppbv by AD 2000 (Assanov et al., 2007). The magnitude and the timing of inferred changes are in agreement with what is known about the sources of atmospheric CO. Overall, the Berkner Island firn data establish a link between the real-time measurements of the present day atmosphere and the ice core measurements. There is no indication that CO levels are altered via *in situ* chemistry in the firn, suggesting that ice cores likely contain a true atmospheric record.

Figure 1 CO measurements in firn air from Berkner Island, Antarctica (Assanov et al., 2007). Data from the top 40 m are impacted by seasonal CO variations at the surface. The data between 40 and 60 m store information on how the annual mean CO levels changed over Antarctica during the twentieth century.

CO has been measured in multiple ice cores from Greenland and Antarctica, using a 'wet' extraction technique (Haan and Raynaud, 1998; Haan et al., 1996). The Greenland measurements (Figure 2 – top panel) are all from the dry-drilled (no drilling liquid) Eurocore from Summit (72.6° N, 37.5° W). During the time period before AD 1650, the measurements display high scatter and remain above 100 ppbv. After AD 1650, CO levels remain at 90–100 ppbv until 1850, then gradually rise to 110 ppbv in AD 1950. There is considerably less scatter in the data for the AD 1650–1950 period and the CO rise between AD 1850 and 1950 is consistent with the timing of the methane increase due to increasing anthropogenic activities. Of the two discrete groups in the Greenland CO record, only the period since 1650 appears to reflect true atmospheric variations. The ice core samples with elevated CO levels contain more total organic material than the ones with no excess CO. The apparently successful recovery of a true atmospheric record from the shallower depths of this core with identical experimental procedures suggests that oxidation of organic matter contained within the ice is the likely cause of the CO elevation (Haan and Raynaud, 1998).

The Antarctic CO measurements are from three different cores dry-drilled at two different sites in East Antarctica (Figure 2). The younger samples for years AD 1850–1920 are from the D47 ice core (67.2° S, 154.0° E). The older samples that predate AD 1400 are from two different Vostok ice cores (78.5° S, 106.9° E). The CO mixing ratio in the Antarctic samples mostly stays within 50–60 ppbv, with averages of 57 ± 1 ppbv ($\pm 1\sigma$) and 51 ± 2 ppbv in D47 and Vostok samples, respectively (Haan and Raynaud, 1998). Low sample-to-sample variability and the close agreement between the two data sets suggest the Antarctic CO record reflects real atmospheric variations, although it is not yet possible to rule

Figure 2 CO measurements in polar ice cores from Greenland (upper panel) and Antarctica (lower panel). Upper panel – CO data (blue squares) from the Eurocore ice core dry-drilled at Summit, Greenland (Haan and Raynaud, 1998; Haan et al., 1996). The gray band represents the CO levels in the modern-day high-latitude northern hemisphere. Lower panel – CO measurements in the D47 ice core from East Antarctica (blue squares – Haan et al., 1996) and in two different ice cores drilled at Vostok, East Antarctica (red squares – Haan and Raynaud, 1998). The gray band represents the CO levels in the modern-day high-latitude southern hemisphere.

out artifactual enhancement. Antarctic ice cores generally contain fewer impurities (organic and inorganic) than the Greenland ice cores because Antarctica is more isolated from other continents. Consequently, Antarctic ice cores are better candidates for measurements of ultra-trace gases such as CO.

Considering the substantial rise in atmospheric CH₄ during the twentieth century, it is interesting that the mean CO levels in the Antarctic record are mostly within the range measured over Antarctica today. As discussed previously, the CO mixing ratio measured at the bottom of the firn at Berkner Island (Figure 1) is 45 ± 2 ppbv, which implies that the actual atmospheric levels were less than 40 ppbv around AD 1900. The difference between the firn air results and the D47 measurements for the same period is about 20 ppbv. This is larger than the reported precision of the measurements and may suggest that the ice core CO levels in the D47 core are elevated, albeit at a much lower level than what is observed in the Eurocore from Greenland. Haan and Raynaud (1998) compared the impurity levels in their Greenland and Antarctic samples and calculated that the CO mixing ratios in their Antarctic samples could contain ~ 10 ppbv of excess CO.

New ice core CO measurements are forthcoming. A recent record from the Law Dome ice cores in Antarctica (Ferretti et al., 2005) shows CO mixing ratios at ~ 50 ppbv between AD 1500 and 1700, in apparent agreement with the D47 and Vostok records. However, the CO levels in Law Dome ice cores stay above 60 ppbv between AD 0 and 1500, exceeding 80 ppbv for 400 years around AD 800 (Ferretti et al., 2005). The Vostok record is fairly coarse resolution and does not contain any samples between AD 600 and 900 (Figure 2); however, the difference between the means of these two records appears to be significant. Overall, there is circumstantial evidence for low-level artifactual CO enhancement in the Antarctic ice cores. Contemporaneous measurements from multiple Antarctic sites with different impurity levels are needed to resolve this outstanding issue.

There is every reason to expect more extensive ice core records of CO. Such measurements will likely lead to reconstruction of true CO variations in the Antarctic atmosphere during the Holocene. Most recently, a 650-year-long record of CO and stable isotopes of CO ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) has been recovered from Antarctic ice cores, suggesting that CO changes in the preindustrial atmosphere have been dominated by large variations in biomass burning (Wang et al., 2010). The prospects of developing a continuous northern hemisphere CO record may not be as good because of the high impurity levels in Greenland ice cores. However, it is possible that a partial record can be retrieved from the Greenland ice cores, providing a baseline for the northern hemispheric mean CO levels in the preindustrial atmosphere.

Carbonyl Sulfide

Carbonyl sulfide (COS) is the most abundant sulfur gas in the troposphere. Its tropospheric lifetime is 2–4 years, allowing for mixing between hemispheres. The mean COS mixing ratio was ~ 480 ppt in the southern and 490 ppt in the northern hemispheres based on atmospheric measurements over the 5 years between 2000 and 2005 (Montzka et al., 2007). In

the stratosphere, COS oxidizes to form sulfate aerosols, which reduce the amount of solar radiation that reaches the earth. It is estimated that COS contributes about half of the background stratospheric sulfate during periods of volcanic inactivity (Weissenstein et al., 2006), implying that large variations in the atmospheric COS levels would have an impact on global climate.

Natural COS sources include terrestrial and oceanic emissions. Anthropogenic emissions are linked to industrial production of synthetic fibers. COS is oxidized by OH in the troposphere and taken up by soils but the most significant removal process is uptake by terrestrial vegetation (Kettle et al., 2002; Montzka et al., 2007). The removal of COS by terrestrial biota has recently drawn considerable scientific interest (Campbell et al., 2008; Sandoval-Soto et al., 2005; Seibt et al., 2010; Xu et al., 2002). COS is taken up by plants during photosynthesis alongside CO₂. This process represents a net COS uptake, because unlike CO₂, COS is not respired back into the atmosphere. Consequently, ice core COS records could potentially reveal atmospheric COS variability caused by changes in global photosynthetic activity and therefore help constrain the causes of past CO₂ variations in the atmosphere.

First data on atmospheric COS variability during the periods that predate the instrumental record were obtained from polar firn air measurements at two sites in Antarctica and one in the Canadian Arctic (Sturges et al., 2001b). This study was followed up by additional firn air measurements at South Pole, Antarctica and the first COS measurements in a shallow ice core from Siple Dome, Antarctica that displayed consistency with each other and with the available instrumental data during periods of overlap (Montzka et al., 2004). These observations offer evidence that mean COS levels in the preindustrial atmosphere were 300–350 ppt and that they peaked at ~ 550 ppt during the latter half of the twentieth century, presumably as a result of rising anthropogenic emissions. In agreement with these results, first measurements in shallow Greenland ice cores indicate that the COS abundance in the northern hemisphere atmosphere between 1700 and 1900 was in the 300–350 ppt range (Aydin et al., 2007).

More recent measurements from a South Pole ice core provide a continuous COS record for the last 2000 years when combined with the earlier Siple Dome record (Figure 3). The Siple Dome and South Pole data display consistency where they overlap and most neighboring data points within both data sets exhibit agreement. These are strong indicators that the COS levels measured in these two ice cores from Antarctica reflect true atmospheric mixing ratios over the last 2000 years. There are a few cases when the measured COS mixing ratio in individual samples is elevated with respect to the overall trend and the neighboring data points. It is unlikely these outliers reflect true atmospheric levels. Instead, they may be due to intermittent contamination introduced during extraction and analysis of the ice core samples or *in situ* production of COS via a yet unidentified chemical mechanism.

Excluding the outliers, the average COS mixing ratio in the South Pole record is 310–350 ppt, with an overall increasing trend of ~ 1.8 ppt per 100 years (Aydin et al., 2008). One major concern about COS ice core measurements has been potential *in situ* loss of COS via hydrolysis in liquid-like layers

Figure 3 COS measurements in polar ice cores. The Siple Dome (red triangles) and the South Pole (blue squares) data are consistent during the period of overlap. There are outliers in both the South Pole (open squares) and Siple Dome (open triangles) data sets. The gray band represents the mean COS mixing ratio in the southern hemisphere between CE 2000 and 2005 (Montzka et al., 2007). The blue band is the mean of the South Pole record, excluding the outliers. The thicknesses of the gray and blue bands represent the estimated uncertainty in the reported means.

within the ice matrix (Assonov et al., 2005). It is possible that this long-term increasing trend is linked to slow hydrolysis of COS in the ice sheet. However, when this trend is extrapolated to the present day, the calculated COS increase between the preindustrial times and the end of the twentieth century is much smaller than what is apparent in the ice core and firn air records, providing strong evidence that anthropogenic emissions during the twentieth century had a profound impact on the atmospheric mixing ratio of this gas. The South Pole record also displays higher than average COS levels between CE 1000–1200 and CE 1500–1700, and lower than average mixing ratios between CE 100 and 700. Such anomalies may be due to changes in the biogeochemical cycling of COS as a response to variations in the global climate. Longer-term measurements from different ice cores will help determine whether these really are periods of COS variations in the atmosphere that are climatically driven. The currently available data suggest COS can be measured in ice cores from both hemispheres over millennial time scales. Extending the record to longer time scales will require more detailed studies on the hydrolysis of COS in ice cores, which is strongly temperature dependent. Measurements in contemporaneous samples with different temperature histories will likely reveal the significance of *in situ* COS loss to hydrolysis in ice cores.

Methyl Chloride

Methyl chloride (CH_3Cl) is an abundant halocarbon with a mean tropospheric mixing ratio of ~ 550 ppt. It is the largest source of chlorine in the stratosphere, thus considered an important ozone-depleting gas (Montzka et al., 2003b). Emissions from tropical vegetation and biomass burning are considered to be the two most important sources of CH_3Cl . Direct emissions linked to industrial activities are deemed insignificant and oceanic emissions are large but balanced with oceanic uptake that is almost equally large, resulting in a relatively small net source. Oxidation with OH is the most important loss pathway for CH_3Cl , with additional removal by oceanic

uptake and degradation in soils, resulting in a tropospheric lifetime of just over 1 year (Hamilton et al., 2003; Khalil and Rasmussen, 1999; Tokarczyk et al., 2003; Yokouchi et al., 2002).

There have been several CH_3Cl firn air studies at various sites in Antarctica (Aydin et al., 2004; Butler et al., 1999; Kaspers et al., 2004; Trudinger et al., 2004). The firn air records consistently displayed evidence that atmospheric CH_3Cl levels rose about 40–50 ppt during the twentieth century, despite relatively small discrepancies regarding the mean levels measured at different Antarctic sites (Trudinger et al., 2004). First measurements in a shallow ice core from Siple Dome, Antarctica, showed that mean CH_3Cl levels were ~ 500 ppt between CE 1700 and 1900, in agreement with the inferred CH_3Cl abundance in the preindustrial atmosphere based on the firn air measurements (Aydin et al., 2004).

A longer CH_3Cl record was obtained from the same South Pole ice core (Williams et al., 2007) that was used for the COS measurements shown in Figure 3. These measurements provide a continuous CH_3Cl record for the last 2000 years when combined with the earlier Siple Dome observations (Figure 4). There is consistency between the two data sets during the time of overlap between CE 1700 and 1800. There are a few outliers in the South Pole data set; the remaining measurements exhibit good sample-to-sample agreement between neighboring data points within the uncertainties, suggesting that the impact of potential experimental artifacts is minimal. The average CH_3Cl mixing ratio in the South Pole ice core is ~ 460 ppt, or 70–80 ppt lower than the annual mean levels observed in Antarctica today. The South Pole ice core data exhibit a positive trend of 3 ppt per 100 years (Williams et al., 2007). This slow increase may be a real atmospheric trend or may indicate slow degradation of CH_3Cl within the ice cores. Measurements from different sites are required to confirm the observed long-term increasing trend. The South Pole data also reveal centennial scale variability that appears to be correlated with climatic shifts during the last millennia, suggesting a warming global climate may lead to increased CH_3Cl levels in the atmosphere (Williams et al., 2007).

Figure 4 CH_3Cl measurements in polar ice cores. The Siple Dome (red squares) and the South Pole (blue squares) data are consistent during the period of overlap. The gray band represents the annual mean CH_3Cl mixing ratio in the southern hemisphere today (Montzka et al., 2007). The blue band represents the average of CH_3Cl measurements in the South Pole ice core. The thicknesses of the gray and blue bands represent the estimated uncertainty in the reported means.

CH_3Cl has also been measured in two deep ice cores from Siple Dome, West Antarctica, (Saltzman et al., 2009) and Dome Fuji, East Antarctica (Saito et al., 2007). These are the first ultra-trace gas records that extend through the entire Holocene and into the last glacial period (Figure 5). During the Holocene, the mean CH_3Cl level in the two deep cores is 500–600 ppt, generally exhibiting good agreement where they overlap, although there are only a few data points from the Dome Fuji ice core. When compared with the shorter late Holocene record from the South Pole ice core (Figure 4), the CH_3Cl data from the deep Siple Dome ice core are more scattered and display 50–150 ppt elevation in most samples that overlap with the South Pole record. Intermittent CH_3Cl production in basal firn at the warmer Siple Dome site may be the reason (Saltzman et al., 2009). Surprisingly, parts of a short preindustrial record measured in two shallow Greenland ice cores also indicated *in situ* production of CH_3Cl that likely occurred in the firn (Aydin et al., 2007). It is not clear whether the CH_3Cl ‘excess’ observed in Holocene ice from Greenland and Siple Dome, Antarctica, are causally linked. While Greenland ice cores contain high levels of impurities, Siple Dome is the warmest site. The potential impacts of site temperature and ice impurity levels on CH_3Cl production in the firn need to be examined with additional firn air and ice core measurements.

There are large discrepancies between the Siple Dome and Dome Fuji measurements from the last glacial period, with marked enhancements apparent in the Dome Fuji data (Figure 5). It has been shown that the excess CH_3Cl in the entrapped bubbles is correlated with elevated dust levels in the enclosing ice from the last glacial period at the Dome Fuji site (Saito et al., 2007). There is no indication of a correlation between measured CH_3Cl mixing ratio and the dust content of the enclosing ice at the Siple Dome site except possibly at the height of the Last Glacial Maximum (~25 ka BP) when the dust levels peak (Mayewski and Maasch, 2006; Saltzman et al., 2009). It should be noted that the Siple Dome ice core contains considerably less dust than the Dome Fuji ice core. Earlier during the last glacial period between 30 and 70 ka BP, Siple

Figure 5 CH_3Cl measurements in polar ice cores. The Siple Dome (blue squares) and the Dome Fuji (black triangles) data from the Holocene are consistent during periods of overlap. The Dome Fuji CH_3Cl data from the last glacial period are considerably elevated with respect to the contemporaneous Siple Dome measurements. The red dashed line represents the mean CH_3Cl mixing ratio in the South Pole ice core shown in Figure 4.

Dome CH_3Cl measurements display low variability between adjacent samples and stay mostly at or below the late Holocene levels measured in the South Pole ice cores (Figure 5). Collectively, these results suggest *in situ* production of CH_3Cl might occur when the dust content of the ice cores exceeds a certain threshold, although the mechanisms are unclear. It cannot be ruled out that the Siple Dome measurements from 30 to 70 ka BP include a small bias due to dust related *in situ* production of CH_3Cl as the entire Antarctic continent experienced enhanced dust deposition during the last glacial period. The CH_3Cl mixing ratio measured in the Siple Dome glacial ice cores during 30–70 ka BP may represent only an upper limit.

Methyl Bromide

Methyl bromide (CH_3Br) contributes significantly to ozone depletion in the stratosphere because it is an abundant

bromine (a halogen) containing gas. It is produced naturally in oceanic and terrestrial biogeochemical systems, and during biomass burning. In addition, it has been industrially manufactured to be used as a fumigant in agriculture and other industries during the twentieth century (Clerbaux et al., 2006). It is taken up by oceans and soils, and oxidized in the atmosphere by OH, resulting in a mean atmospheric lifetime of ~ 0.7 years (Yvon-Lewis and Butler, 1997). Following the recognition of its prominent role in depletion of stratospheric ozone layer, it was included in the Montreal Protocol and its amendments. Restrictions on CH_3Br use as a fumigant started in 1998. Consistent with the timing of the regulatory actions, the atmospheric abundance of CH_3Br peaked in 1998–1999 at 10–11 ppt in the northern hemisphere and 8–8.5 ppt in the south (Montzka et al., 2003a). Since then, its atmospheric mixing ratio declined considerably, especially in the north where most of the anthropogenic emissions used to occur (Montzka et al., 2003a; Yokouchi et al., 2002; Yvon-Lewis et al., 2009).

CH_3Br measurements in firn air at four different sites in Antarctica revealed that the atmospheric mixing ratio of this gas increased by about 3 ppt during the twentieth century, with 2 ppt of the increase occurring after the 1950s. In contrast, measurements in firn air from the Canadian Arctic and Greenland displayed increasing CH_3Br mixing ratios in deeper firn, suggesting *in situ* CH_3Br production close to the base of the firn (Butler et al., 1999; Sturges et al., 2001a). These results indicate that it could be possible to develop a southern hemisphere CH_3Br record with measurements in Antarctic ice cores, but it was unlikely that the same could be done in the northern hemisphere.

The first ice core CH_3Br measurements from a shallow core from Siple Dome, Antarctica, displayed first direct evidence that the CH_3Br abundance in the pre-twentieth century atmosphere was below 6 ppt (Saltzman et al., 2004). In contrast, CH_3Br mixing ratios from two Greenland shallow ice cores were higher than the peak northern hemisphere levels in all the samples, displaying high scatter with little or no consistency between neighboring data points (Aydin et al., 2007). These first sets of measurements suggest it is highly unlikely that a northern hemisphere CH_3Br record will be recovered using ice cores from Greenland and the Canadian Arctic.

CH_3Br was analyzed in the same South Pole ice core that was used in COS and CH_3Cl measurements. The South Pole data provide a continuous CH_3Br atmospheric history for the last 2000 years when combined with the shorter Siple Dome record from Antarctica (Figure 6). The mean CH_3Br mixing ratio in the South Pole ice core is 5.4 ± 0.6 ppt ($\pm 1\sigma$), with no discernable long-term trend but variations at 10–20% level are evident over centennial time scales (Saltzman et al., 2008). This centennial variability could be driven by changes in climate or may be related to artifactual CH_3Br enhancement due to unknown factors. The lack of a long-term trend in the 2000-year-long record is strong evidence against a time-dependent chemical loss or production within the ice cores. The stability of the CH_3Br mixing ratios over the measurement periods provides a strong constraint on how low we can expect atmospheric CH_3Br levels to drop as a result of the measures taken under the Montreal Protocol. Longer records from Antarctic ice core records are needed to investigate the impacts of significant changes in global climate on the atmospheric CH_3Br levels and the state of the stratospheric ozone layer.

Ice Core Air Extraction Methods

A ‘wet’ extraction technique was used for the CO measurements (Haan and Raynaud, 1998; Haan et al., 1996). Prior to the extraction, the outer surface of an ice cores sample (~ 50 g) is shaved off for eliminating potential contaminants on the surface. The sample is then placed under vacuum in a glass extraction vessel. During the first stage of the extraction, the ice core sample is melted by immersing the glass vessel in a hot water bath. While the sample melts, the air trapped inside the sample collects in the headspace inside the glass vessel. Once melting is complete, the hot bath is replaced with a cold one to refreeze the sample. Slow refreezing from bottom upward results in bubble-free ice and ensures close to 100% recovery of the ice core air.

COS, CH_3Cl , and CH_3Br measurements were conducted using a ‘dry’ extraction method, in which the entrapped air is liberated in a cold vacuum chamber without melting the ice core samples (Aydin et al., 2007). After cleaning the outer

Figure 6 CH_3Br measurements in polar ice cores. The Siple Dome (red squares) and the South Pole (blue squares) data are consistent during the period of overlap. The gray band represents the peak annual mean CH_3Br mixing ratios observed in the southern hemisphere during 1997–1999 (Montzka et al., 2007). The blue band represents the mean CH_3Br mixing ratio in the South Pole ice core. The thicknesses of the gray and blue bands represent the estimated uncertainty in the reported means.

surfaces, ice core samples (400–500 g) are placed on a sharp cutting surface welded inside a stainless steel vacuum chamber. Once the chamber is isolated and pumped out, it is put into linear motion device that results in the sample sliding back and forth over the cutting surface. In 15 min, most of the ice core sample is shredded and the liberated air is collected in the vacuum chamber. This method results in ~70% recovery of the air trapped in the ice core.

Regardless of the extraction technique that has been used, very small amounts of air are available for measurements, requiring highly sensitive analytical instrumentation. The COS, CH₃Cl, and CH₃Br have been measured in a gas chromatogram–mass spectrometer (GC–MS) system that makes use of high-resolution mass spectrometry for improved sensitivity, which enables ppt level measurements in ice core air samples that often do not exceed 20–30 ml STP (standard temperature and pressure) in size (Aydin et al., 2007). The CO measurements are generally carried out with a GC equipped with a reduction gas detector.

Considerations for Future Work

The potential of the ice cores in preserving a true archive of past atmospheric ultra-trace gas variations remains largely unexplored. In addition to the compounds covered in this article, ethane and carbon disulfide (Aydin et al., 2007), and stable isotopic ratios of CO (Wang et al., 2010) have been measured in ice core air. It is safe to assume that there will be attempts to add other ultra-trace gases (e.g., nonmethane hydrocarbons) to this list, and clearly more work is required on the verification of the already existing data with multiple ice cores from a variety of sites. Broader participation by the international scientific community and involvement of additional laboratories are required for faster progress.

History of Nitrous Oxide from Ice Cores

A Schilt, University of Bern, Bern, Switzerland

Introduction

As a trace gas in the atmosphere, nitrous oxide (N_2O) is part of the global nitrogen cycle (Gruber and Galloway, 2008) and important because it acts as a strong greenhouse gas and is involved in the destruction of stratospheric ozone. The atmospheric burden of N_2O dramatically increased over the last centuries, resulting in a current atmospheric concentration of 322 parts per billion by volume (ppbv). This $\sim 20\%$ increase with respect to preindustrial levels of ~ 270 ppbv contributes $\sim 6\%$ to the anthropogenic radiative forcing of all long-lived greenhouse gases. The increase originates from anthropogenic N_2O emissions from expanding and fertilized agricultural lands, burning of fossil fuels and biomass, and industrial processes. Further, human activities (human excreta, landfills, and atmospheric deposition) enhance the input of nitrogen compounds into various ecosystems, leading to significant anthropogenic N_2O emissions from, for example, coastal and open oceans, rivers, and estuaries. Anthropogenic N_2O emissions currently account for ~ 6.7 Tg of N per year, while natural N_2O sources emit ~ 11 Tg of N per year (IPCC, 2007). Nitrification and denitrification are the fundamental microbiological processes responsible for N_2O production in terrestrial and marine ecosystems, while minor N_2O emissions derive from chemical processes in the atmosphere. About two thirds of the total natural N_2O emissions stem from soils, where the emission strength not only depends on the water-filled pore space and, thus, oxygen availability, but also on nitrogen input, temperature, and soil structure. About one third of the total natural N_2O emissions stems from marine sources, which are highest in equatorial and coastal upwelling regions, the Southern Ocean ($40\text{--}60^\circ\text{S}$), the North Pacific, and the Arabian Sea. The major sink of N_2O is its destruction by photodissociation, followed by chemical reactions with excited oxygen. Both processes take place only in the stratosphere, making N_2O an inert gas in the troposphere. Consequently, N_2O has a relatively long atmospheric life time of ~ 120 years, and is globally well mixed. The strength of the stratospheric sink depends on the amount of solar UV radiation, which is needed for the photodissociation of N_2O , and on the exchange rate of air between troposphere (where N_2O is produced) and stratosphere (where N_2O is destroyed). Since there are no indications for substantial changes in either the solar irradiance or the exchange rate of air between troposphere and stratosphere, the strength of the N_2O sink is commonly considered as remaining constant, an assumption that is also supported by modeling studies (Martinerie et al., 1995).

In the accumulation zones of polar ice sheets, snow is stored layer by layer and advected downward. In the firn column (the upper 50–120 m of an ice sheet), atmospheric air can circulate through the pore space. Below, where the densification process of snow to ice is completed, air bubbles are enclosed in the ice. Accordingly, the past evolution of the

atmospheric composition is recorded in the ice and can directly be reconstructed by analyses of air extracted from ice cores recovered from the polar ice sheets of Greenland and Antarctica. To date, a composite record consisting of measurements from various studies and ice cores provides a complete insight into the evolution of atmospheric N_2O over the last 140 000 years (140 ka) (Schilt et al., 2010b). Interglacial N_2O records even reach back to as far as 800 ka before present (BP) (Spahni et al., 2005; Schilt et al., 2010a). An overview of N_2O records is also provided in Wolff and Spahni (2007).

Analytical Techniques

The analytical techniques applied to measure past N_2O concentrations in air extracted from polar ice cores are very similar to the techniques used for carbon dioxide (CO_2 , see [CO₂ Studies](#)) and methane (CH_4 , see [Methane Studies](#)). Often, the air extracted from one single sample is analyzed for more than one trace gas. In a first step, an ice sample (40–600 g) is cut with a band saw and put in a sealed glass or stainless steel container, which is then connected to a vacuum system in order to remove ambient air. Different extraction techniques have provided reproducible results for N_2O concentrations. These techniques include (i) dry extraction with a mill or cheese grater system (e.g., Machida et al., 1995; Sowers, 2001), (ii) sublimation extraction (Güllük et al., 1998), (iii) melt extraction by subsequent refreezing of the melt water (e.g., Chappellaz et al., 1997; Flückiger et al., 1999). Following the extraction, the N_2O concentration is determined using either a laser spectrometer or, up to now more commonly applied, a gas chromatograph equipped with an electron capture detector. Measurements are calibrated using standard gases of known concentrations. The obtained N_2O concentrations are corrected based on measurements with bubble-free ice and standard gases, ensuring that potential contamination and solubility effects do not bias the results. Typically, the reproducibility of N_2O concentration measurements is 5.6 ppbv (as determined by measuring neighboring samples with the melt extraction, Schilt et al., 2010b).

Reliability of N_2O Records from Polar Ice Cores

Consistent results have been obtained for past N_2O concentrations on centennial, millennial, and glacial–interglacial time scales with different extraction techniques and analysis systems, located in different labs. Nevertheless, N_2O records measured along polar ice cores are occasionally affected by *in situ* production of N_2O in the ice. Measurements affected by *in situ* production show concentrations above the atmospheric value at the time of air trapping. Such artifacts are mainly observed in ice from cold (glacial) time intervals, and may originate from

microbiological activities in the ice (Miteva et al., 2007; Rohde et al., 2008). Precautions are needed in order to ensure that all measurements affected by *in situ* production are excluded from the atmospheric records. The applied methods for the exclusion of artifacts include algorithms iteratively detecting outliers in highly resolved records (Flückiger et al., 2004, see also Figure 4), as well as a dust criterion broadly excluding measurements along ice samples with large amounts of impurities (Spahni et al., 2005; Schilt et al., 2010a). Although the exclusion of measurements affected by *in situ* production is done in an empirical way, the remaining atmospheric records from different ice cores are in very good agreement. Such agreement of N₂O records from different ice cores (recovered from both Greenland and Antarctica) is a strong and required validation of the atmospheric origin of the measured concentrations, based on the fact that N₂O is globally well mixed in the atmosphere.

Another issue regarding a reliable reconstruction of atmospheric N₂O concentrations from ice cores is the gravitational enrichment of N₂O in the firn column. However, this effect typically accounts for only ~2 ppbv and is therefore not considered in most studies.

The Last Two Millennia

While many N₂O records from different ice cores and investigators confirm the general trend in atmospheric N₂O concentrations over the last two millennia (Figure 1), the most accurate N₂O record covering this time interval may currently stem from Law Dome (MacFarling Meure et al., 2006). The available records from firn air and ice cores from Greenland and Antarctica are confirmed and extended to present by direct atmospheric measurements, which already record more than the last 30 years. Between AD 0 and 1850, atmospheric N₂O concentrations show a rather stable level with some minor variations of up to ~10 ppbv, for example, reflected in an increase between AD 675 and 810 (MacFarling Meure et al., 2006). Numerous studies indicate N₂O concentrations of ~270 ppbv between AD 1750 and 1850. After AD 1850, the

atmospheric N₂O concentrations drastically increase to today's concentration of 322 ppbv, with a higher increase rate during the second half of the twentieth century. Contemporaneous with this concentration increase, measurements of the isotopic composition of N₂O indicate a decrease in the relative amount of ¹⁸O, ¹⁵N, and position dependent ¹⁵N of N₂O (Sowers et al., 2002; Bernard et al., 2006; Ishijima et al., 2007). This evolution of the isotopic composition is in agreement with an increasing importance of anthropogenic N₂O emissions from agricultural activities since AD 1850.

The Holocene

The first accurate high-resolution N₂O record covering the Holocene (current interglacial) has been measured along the EPICA Dome C (EDC) ice core (Flückiger et al., 2002). This record has then been confirmed by the Greenland Ice Sheet Project 2 (GISP2) ice core (Sowers et al., 2003), as well as by the EPICA Dronning Maud Land (EDML) and Talos Dome ice cores (Schilt et al., 2010a,b), indicating that all records reveal atmospheric values (Figure 2). Although the N₂O concentrations remain rather stable during the preindustrial Holocene, some significant variations are observed. In the early Holocene, the N₂O concentrations start to decrease from ~270 ppbv and reach minimal Holocene levels of below ~260 ppbv between about 10 and 6 ka BP, followed by a slow increase to the preindustrial level. Some short-term variations may be present, but they are poorly resolved with the current resolution and analytical precision of the measurements.

Assuming that the sink of N₂O has remained constant, the minimal concentrations during the Holocene correspond to a decrease of the total preindustrial source of 3.7%. Assigning the whole decrease to one source type only would either require a decrease of 5.6% or 11.2% of the terrestrial or marine source, respectively (Flückiger et al., 2002). At this point, however, the causes for the observed variations in N₂O concentrations during the Holocene are not yet completely understood.

Figure 1 The evolution of atmospheric N₂O concentrations during the last two millennia. Shown are selected results from various firn air and ice cores (Machida et al., 1995; Battle et al., 1996; Flückiger et al., 1999, 2002; MacFarling Meure et al., 2006; Schilt et al., 2010a,b). Other investigations (not shown here) have also clearly revealed the anthropogenic N₂O increase (e.g., Pearman et al., 1986; Etheridge et al., 1988; Khalil and Rasmussen, 1988; Leuenberger and Siegenthaler, 1992; Dibb et al., 1993; Sowers, 2001). However, the latter studies somewhat differ from the results shown here, either due to calibration inconsistencies, larger scatter, and/or too high preindustrial concentrations. The black line shows a combined data set of direct atmospheric N₂O measurements from the NOAA/ESRL global monitoring division.

Figure 2 High-resolution N_2O records covering the Holocene as measured along the EDC (Flückiger et al., 2002), EDML (Schilt et al., 2010a), Talos Dome (Schilt et al., 2010b), and GISP2 (Sowers et al., 2003) ice cores. Differences, in particular around 10 ka BP, may at least partly be the result of uncertainties in the time scales of the different ice cores. The black line represents a spline with a cutoff period of 1000 years through all given records.

Figure 3 The evolution of atmospheric N_2O concentrations during the last glacial and the transition to the Holocene. Shown is a composite record consisting of measurements along the following ice cores: EDC (Flückiger et al., 1999; Stauffer et al., 2002; Spahni et al., 2005), EDML (Schilt et al., 2010a), NGRIP (Flückiger et al., 2004; Schilt et al., 2010b), Talos Dome (Schilt et al., 2010b), GRIP (Flückiger et al., 1999), and GISP2 (Sowers et al., 2003). The records of different ice cores have been put on a common timescale using CH_4 as a synchronization tool (Schilt et al., 2010b), and a spline with a cutoff period of 1000 years has been calculated through all N_2O measurements (black line). Numbers denominate Dansgaard/Oeschger events.

The Transition from the Last Glacial to the Holocene

The transition from the last glacial to the Holocene marks one of the most extreme warmings in the Earth's climate during the Late Quaternary. First measurements along Antarctic ice cores have already identified a substantial N_2O increase in concert with the termination of the last glacial (Zardini et al., 1989). The N_2O increase has then been quantified to roughly 30% (Leuenberger and Siegenthaler, 1992). More recent measurements, however, are much more precise and yield a detailed and highly resolved insight into the N_2O evolution over the transition from the last glacial to the Holocene (Figure 3).

Around 16 ka BP, N_2O concentrations start to increase from an extremely low level of ~ 200 ppbv. The increase accelerates at 14.5 ka BP, at the same time when CH_4 concentrations jump into the Bolling/Allerød warm period (see Methane Studies). During the latter time interval, N_2O concentrations remain fairly constant at ~ 260 ppbv. In response to the

subsequent Younger Dryas cold period, N_2O concentrations decrease by ~ 30 ppbv. In contrast to CH_4 , the N_2O evolution in response to the Younger Dryas cold period is much smoother, and the strength of N_2O sources always remains above typical glacial values (Flückiger et al., 1999). For the Younger Dryas cold period, Goldstein et al. (2003) have simulated a concentration decrease of ~ 10 ppbv with a coupled climate-biogeochemical model of reduced complexity. The model suggests that a reduced Atlantic thermohaline circulation leads to a stronger stratification within the ocean. As a consequence, total marine N_2O emissions decrease because N_2O production decreases and N_2O storage increases. Since the model only takes into account marine processes, terrestrial emissions may be responsible for the remaining ~ 20 ppbv of the concentration decrease in response to the Younger Dryas cold period. Following the Younger Dryas cold period, N_2O concentrations increase to an early Holocene value of ~ 270 ppbv.

Figure 4 Greenland temperature, CH₄, and N₂O concentrations during the Dansgaard/Oeschger events 17–15 as measured along the NGRIP ice core. (a) Reconstruction of Greenland temperature (Huber et al., 2006). (b) CH₄ concentrations (Huber et al., 2006). (c) N₂O concentrations (Schilt et al., 2010b). Stars remark measurements which are affected by *in situ* production of N₂O in the ice, arrows indicate the location of such artifacts exceeding the limits of the y-axis. Figure adapted from Schilt et al. (2010b).

Since N₂O emitted from terrestrial and marine sources differs significantly in its characteristic isotopic composition, a change in the isotopic composition of atmospheric N₂O can help to decipher the relative contribution of terrestrial to marine sources. For the last 33 ka, measurements along the Taylor Dome ice core indicate that both $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ of N₂O remained fairly constant (Sowers et al., 2003). This suggests that the ratio of terrestrial to marine emissions varied by less than 16%. Additional measurements of the isotopic composition of N₂O will further help to understand the biogeochemical processes responsible for the observed variations in atmospheric N₂O concentrations.

The Last Glacial Epoch

During the last glacial, temperatures are generally reduced, but reconstructions of Greenland surface temperature show rapid oscillations of up to 15 °C (Huber et al., 2006). These so-called Dansgaard/Oeschger events take place on millennial time scales and have counterparts in the southern hemisphere (see [Correlations Between Greenland and Antarctica, Greenland Stable Isotopes](#)). In general, N₂O concentrations are low during cold time intervals and strongly increase during Dansgaard/Oeschger events, occasionally reaching concentrations as high as during the Holocene. This is visible in a composite N₂O record, which consists of measurements along numerous ice cores and which covers without any gaps the last glacial–interglacial cycle (Figure 3). Further, high-resolution N₂O records have revealed numerous and detailed characteristics of the N₂O evolution during Dansgaard/Oeschger events. (i) The N₂O amplitude in response to Dansgaard/Oeschger events increases approximately linearly with the duration of the events. In contrast to CH₄, however, the amplitude of N₂O during Dansgaard/Oeschger events does not show any relationship with solar insolation (Flückiger et al.,

2004). (ii) For long-lasting Dansgaard/Oeschger events, N₂O concentrations start to increase several hundred years before the rapid rise in Greenland temperature and CH₄ concentrations (one example is shown in Figure 4), while the available records for shorter events are less clear (Flückiger et al., 2004). A modeling study has suggested that the early increase results from a long-term adjustment of the nitrate and oxygen inventories in the upper ocean following a substantial reduction of the Atlantic Meridional Overturning Circulation (Schmittner and Galbraith, 2008). (iii) Although starting earlier, the N₂O increase lasts significantly longer than the CH₄ increase at the beginning of Dansgaard/Oeschger events, and is completed within some hundred years. The longer-lasting increase can mostly be explained by the differences in atmospheric life times, which are ~120 and ~10 years for N₂O and CH₄, respectively (Flückiger et al., 2004). On the other hand, it appears that the reduction of the N₂O source at the end of the Dansgaard/Oeschger event 8 is slower than the reduction of the CH₄ source (Flückiger et al., 1999). (iv) In the course of the Dansgaard/Oeschger events 17–15, Greenland temperature shows large variations on centennial time scales (Figure 4). While CH₄ concentrations closely follow the temperature evolution, N₂O concentrations are not affected by the oscillations in Greenland temperature. Given that the atmospheric life times of the two gases can explain only parts of the differences, parallel emission changes in the sources of CH₄ and N₂O can be excluded for these centennial timescale variations (Schilt et al., 2010b).

Explaining the causes of the observed changes in atmospheric N₂O concentrations remains a challenging task. Some insight may come from the analysis of marine sediment cores. For instance, considerable enhancement of the water column denitrification in the Arabian Sea corresponds to the N₂O variations reconstructed in response to Dansgaard/Oeschger events (Suthhof et al., 2001; Pichevin et al., 2007). Since denitrification in the Arabian Sea substantially contributes to

Figure 5 Atmospheric N_2O concentrations (Flückiger et al., 2002; Stauffer et al., 2002; Spahni et al., 2005; Schilt et al., 2010a) and a proxy of temperature changes over Antarctica (relative to the average of the last 1000 years, Jouzel et al., 2007) from the EDC ice core covering the last 800 ka. Along the EDC ice core, glacial time intervals are affected by *in situ* production of N_2O and, thus, do not allow for a reconstruction of atmospheric N_2O concentrations. The star outside the graph indicates the current N_2O concentration of 322 ppbv. Gray shadows mark interglacials, which are arbitrarily defined as time intervals with a temperature not more than 3°C colder than the last 1000 years. Numbers denote Marine Isotope Stages.

the global marine N_2O source, such changes could contribute to the observed variations in atmospheric N_2O concentrations. However, the large variations in CH_4 concentrations, which are driven by terrestrial sources only, point to substantial changes in the terrestrial biogeochemical cycles as well.

Previous Interglacials

To date, there exist only a few ice cores containing ice from previous glacial–interglacial cycles. All of them are unfortunately affected to various degrees by *in situ* production of N_2O in most of the available glacial ice, which so far precludes a detailed insight into the evolution of atmospheric N_2O concentrations during glacial time intervals beyond the last glacial. Nevertheless, atmospheric N_2O concentrations are available for all interglacials of the last 800 ka (Figure 5).

As in the course of the last glacial–interglacial cycle, N_2O concentrations vary in line with climate, showing high concentrations in warm phases and low concentrations in cold phases. Today's N_2O concentration of 322 ppbv considerably exceeds the natural variation range of ~ 200 – 300 ppbv as determined from the reconstructions of the last 800 ka. While the greenhouse gases CO_2 and CH_4 show lower values for the cooler interglacials between 440 and 800 ka BP compared to the interglacials of the last 440 ka, N_2O concentrations show increased levels. At the end of most interglacials, N_2O

concentrations remain on interglacial levels several thousand years longer than CH_4 concentrations, the latter starting to decrease synchronously with Antarctic temperature (Schilt et al., 2010a). Although the EDC record suffers from large gaps in the glacial N_2O record due to *in situ* production of N_2O in the ice, millennial timescale N_2O variations are observed throughout the last 800 ka. Similar to the Dansgaard/Oeschger events observed during the last glacial, these N_2O events occur contemporaneously with variations in CH_4 concentrations and show a linear relationship between amplitude and duration. These similarities suggest that the underlying mechanism driving the Dansgaard/Oeschger events of the last glacial may also be active throughout the last 800 ka (Schilt et al., 2010a).

Introduction

Radioisotopic dating techniques in the earth sciences are used for the determination of absolute ages for events and processes in the history of the Earth and the solar system. These techniques are based on the decay of radioactive isotopes that occur in our natural environment. Radioactive isotopes that are useful as geochronometers can be split into two groups: radioactive isotopes with long half-lives that have been present since the origin of our solar system (half-lives $>\sim 500$ million years) and radioactive isotopes with short half-lives (generally half-lives $<\sim 10$ million years). The radionuclides in the latter group are steadily produced on the Earth's surface. Examples of these include the intermediate daughter products of the uranium and thorium decay series and the stable lead isotopes that are used in U-series dating, as well as radioactive nuclides formed by interaction of cosmogenic rays in the atmosphere and uppermost layers of the lithosphere which are used in terrestrial cosmogenic nuclide dating, including ^{14}C . These are important techniques for dating Quaternary processes and are described elsewhere in this encyclopedia.

Isotope geochronometers based on isotopes with long half-lives, including the K/Ar method, rely on the *accumulation of radiogenic daughter isotopes* and consequently lose sensitivity rapidly toward very young rocks because of the low accumulation rates of radiogenic daughter isotopes. Most dating techniques are *radioisotopic* or *isotopic* techniques that are based on the determination of the ratio of the radioactive parent isotope to the radiogenic daughter isotope as a function of time by isotope-ratio mass spectrometry. By contrast, measurement of the parent radioisotope, as in the ^{14}C technique, gives the

highest sensitivity in the youngest materials. While ^{14}C dating is an excellent method for the youngest ~ 25 ka and an adequate technique in the 25–50 ka age range, virtually all radioisotope methods based on isotopes with long half-lives struggle in the youngest part of the timescale (i.e., in the late Quaternary).

Most radioisotopes with long half-lives occur in trace elements in natural substances, for example, ^{87}Rb , ^{235}U , ^{238}U , ^{147}Sm , ^{187}Re , usually in ppm concentration levels. The radioactive isotope of potassium (^{40}K ; half-life 1.25×10^9 years) is the only long-lived radioisotope occurring in a major element of the continental crust (the average continental crust has a K_2O content of 1.1% and the radioactive isotope ^{40}K has an abundance, $^{40}\text{K}/\text{K}_{\text{total}}$, of 0.01167%; [Garnier et al., 1975](#)). Because of the relatively high ^{40}K concentrations in rocks and minerals, the radiogenic daughter isotope ^{40}Ar , commonly designated $^{40}\text{Ar}^*$, grows more rapidly and hence can be more readily detected even in very young rocks. Since the 1950s, the detection limit and the analytical precision of the K/Ar method have increased as the result of technical advances, which now allow for the dating of K-bearing volcanic and magmatic rocks spanning most of the Quaternary.

Historical Development of K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ Dating Methods

Radioactivity of potassium has been known since the first decade of the twentieth century ([Campbell and Wood, 1906](#)), and the anomalously high abundance of ^{40}Ar in the Earth's atmosphere was first associated with the radioactivity of natural potassium in the 1930s ([von Weizsaecker, 1937](#)). ^{40}Ar

anomalies in K-bearing geological materials were first reported in the late 1940s, providing the basis for the development of the K/Ar dating method (Aldrich and Nier, 1948). Continuing developments in vacuum and mass spectrometer technology, in particular in Minnesota and Berkeley (Nier, 1950; Reynolds, 1956), allowed the measurement of minute ^{40}Ar anomalies associated with radioactive decay in Quaternary minerals and rocks since the late 1950s. This early interest in dating Quaternary processes is illustrated by the publication of 1.6–1.7 Ma ages for Sutter Butte rhyolite in the Sacramento Valley (Curtis et al., 1956), and for basalt from East African hominid sites at Olduvai Gorge (e.g., Curtis and Evernden, 1962). In the early 1960s, geochronologists at the US Geological Survey, Menlo Park, and at the Australian National University, Canberra, published the first absolute calibrations of the geomagnetic reversal timescale (e.g., Cox et al., 1963; McDougall and Tarling, 1963), thus providing the geology community for the first time with a widely applicable method for the determination of absolute timescales of the Earth's history. This K/Ar calibrated geomagnetic reversal timescale provided the foundations for the scientific proof of sea floor spreading at the mid-oceanic ridges (Vine and Matthews, 1963) and hence the first independent confirmation of the theory of plate tectonics.

The majority of modern K/Ar dating studies are based on the derivative $^{40}\text{Ar}/^{39}\text{Ar}$ technique, where ^{39}Ar is measured as a proxy for ^{40}K , allowing the analysis of smaller single aliquot samples. This approach was developed at the UC Berkeley in the mid-1960s (Merrihue and Turner, 1966). The initial focus of the $^{40}\text{Ar}/^{39}\text{Ar}$ method was to resolve the age information of partially disturbed samples, whereas the exploitation of the potential for increased analytical precision came later (e.g., McDougall, 1981). By the mid-1980s, the University of Toronto team started to use continuous-wave lasers for sample heating instead of furnaces, resulting in a substantial reduction in system blanks. In addition, they replaced the commonly used Faraday collectors with secondary electron multiplier (SEM) detectors, yielding higher sensitivity and thus allowing the detection of 100–1000 times smaller ion-beam intensities. The potential of these new developments for dating the Quaternary was demonstrated in case histories for the Massif Central and Eifel volcanic fields in Europe (Lobello et al., 1987; Van der Bogaard et al., 1987). From the early 1990s, several laboratories acquired the capability to measure young Pleistocene samples with the laser fusion $^{40}\text{Ar}/^{39}\text{Ar}$ method and even explored Holocene volcanism (Hora et al., 2007; Renne et al., 1997; Wijbrans et al., 2011). The most recent advances involve the development of multicollector technology for noble-gas mass spectrometry (Coble et al., 2011; Mark et al., 2009; Rivera et al., 2011), potentially allowing yet another substantial increase in sensitivity.

Independently, French teams have adopted a different approach for measuring extremely small radiogenic ^{40}Ar anomalies by perfecting the conventional K/Ar method (Cassignol and Gillot, 1982). This technique relies on very careful determination of the enrichment in radiogenic ^{40}Ar of unknowns against a standard amount of air argon and has been applied with success to late Pleistocene and Holocene problems (e.g., Quidelleur et al., 2001).

Principle of the Method and Age Calculation

In isotope geochronology, ages can be calculated from the general geochronological age equation. This equation is derived from the observation that the change in the amount of radioactive parent isotope P with time ($-dP/dt$) is proportional to the original amount present (P_0), with λ representing the constant of proportionality ($-dP/dt = \lambda P_0$). In a closed system, the original amount of the parent isotope (P_0) at any time equals the sum of the currently present amounts of parent P and daughter D , that is, $P_0 = P + D$. Solving these equations for t yields the general age equation

$$t = (1/\lambda) \times \ln(D/P + 1) \quad [1]$$

where P is the radioactive parent isotope, D is the radiogenic daughter isotope, t is the time passed since the system became closed in years (*annus*, abbreviated as 'a'), and λ is the decay constant specific for the activity of radioactive isotope P (unit *per annum*, a^{-1} ; Holden et al., 2011).

The decay of ^{40}K (λ) is an example of a dual-decay system, as both ^{40}Ca (~89% by positron (β^+) emission) and ^{40}Ar (~11% by electron capture (e.c.) reactions) are formed as radiogenic daughter isotopes. This means that $P = ^{40}\text{K}$ and $D = (^{40}\text{Ca} + ^{40}\text{Ar})$ in eqn [1]. The total activity of ^{40}K , from which the decay constant is calculated, is the summed activity caused by the e.c. and β^+ emission reactions, and the decay constants thus can be summed with $\lambda = \lambda_{\text{e.c.}} + \lambda_{\beta^+}$. As it is analytically challenging to distinguish the radiogenic ^{40}Ca from the nonradiogenic ^{40}Ca component (natural abundance ^{40}Ca is 96.9% of total Ca) and impractical to measure radiogenic ^{40}Ca and ^{40}Ar simultaneously, the branch yielding ^{40}Ar as radiogenic daughter product ($^{40}\text{Ar}^*$) provides the basis for the K/Ar method.

Taking into account only the $^{40}\text{K} \rightarrow ^{40}\text{Ar}$ decay branch, the general age equation, eqn [1], can be rewritten for the $^{40}\text{K}/^{40}\text{Ar}$ system as

$$t = (1/\lambda) \times \ln[^{40}\text{Ar}/^{40}\text{K} \times \lambda_{\text{e.c.}}/(\lambda_{\text{e.c.}} + \lambda_{\beta^+}) + 1] \quad [2]$$

In the conventional K/Ar technique, ^{40}Ar and ^{40}K are measured independently on different aliquots of the sample. ^{40}K is commonly determined from the total K concentration as measured by analytical chemical techniques, for example, by flame photometry, atomic absorption spectroscopy, optical inductively coupled plasma spectroscopy or X-ray fluorescence spectroscopy techniques, using the natural abundance of ^{40}K to derive an amount of ^{40}K in moles ($^{40}\text{K}/\text{K}_{\text{total}} = 0.01167\%$; Garner et al., 1975). For small samples or in cases of low K concentrations, direct determination of ^{40}K by isotope dilution using a thermal ionization mass spectrometry technique would be appropriate. ^{40}Ar is determined by isotope-ratio mass spectrometry using static analyses in a noble-gas mass spectrometer. Classically, most laboratories used isotope dilution with ^{38}Ar as a tracer isotope of known concentration, but recently laboratories have started to use peak height comparison approaches measuring $^{40}\text{Ar}^*$ beam intensities of unknowns against a mineral standard with a known $^{40}\text{Ar}^*$ content or against ^{40}Ar from an air argon aliquot that comes from a pipette system that has been absolutely calibrated.

Figure 1 (a) Relative contributions of radiogenic, nucleogenic, and air-contaminant argon isotopes shown for an arbitrary Quaternary sample irradiated for $^{40}\text{Ar}/^{39}\text{Ar}$ age determination. (b) Absolute beam intensity differences in an arbitrary Quaternary sample argon mass spectrum. Note that the ^{36}Ar beam is very small and most challenging to measure accurately.

The $^{40}\text{Ar}/^{39}\text{Ar}$ technique requires a neutron activation step for the reaction of ^{39}K nuclei in the sample with fast (2–7 MeV) neutrons to form ^{39}Ar in an (n,p) reaction. Given that the variation of the $^{40}\text{K}/^{39}\text{K}$ ratio in natural substances is small (<0.2%; Garner et al., 1975), the ^{39}Ar signal after neutron activation becomes a proxy for the radioactive parent isotope, ^{40}K . Thus isotopic ages can be calculated from the measured $^{40}\text{Ar}/^{39}\text{Ar}$ ratios because this ratio contains information on the radiogenic daughter, D (from ^{40}Ar), and radioactive parent isotope, P (from ^{39}Ar), which are required for solving the age equation (eqn [1]).

The $^{40}\text{Ar}/^{39}\text{Ar}$ technique has several important advantages with respect to the conventional K/Ar technique because, in the K/Ar technique, absolute concentration determinations for ^{40}K and for ^{40}Ar have to be carried out on two different splits of a sample, whereas with the $^{40}\text{Ar}/^{39}\text{Ar}$ technique the isotope ratio determination can be obtained from a single sample aliquot. The benefit of this procedure is twofold: (1) isotope ratios can be measured much more precisely than absolute amounts, and with increasing instrumental sensitivity increasingly smaller amounts of sample can be dated; and (2) because the D/P ratio information required for solving the age equation is obtained from isotopes of a gas, argon, incremental heating strategies become possible, such as extraction by stepwise degassing of the samples. Incremental heating can be used to test the homogeneity of radiogenic ^{40}Ar in a mineral when partial disturbance of the signal is suspected. It can be used also to extract information on the local K–Ca–Cl chemistry of individual reservoirs contributing to the degassing of a sample at any given temperature, which is of particular importance when whole rock or groundmass samples are measured.

In the $^{40}\text{Ar}/^{39}\text{Ar}$ technique, the age of unknowns is measured against a standard of known age. The irradiation conditions for the production of ^{39}Ar can be accurately and precisely monitored by the standard if the standard and sample are irradiated together in a carefully defined geometry. An irradiation parameter, commonly designated J , can be defined as

$$J = (e^{\lambda t} - 1) / (^{40}\text{Ar}^* / ^{39}\text{Ar}_K) \quad [3]$$

where t is the absolute age of the standard as determined by other techniques such as conventional K/Ar, U/Pb, or cyclostratigraphic dating based on the expression in the geological rock record of climate variation caused by oscillations in the Earth's orbital parameters, $^{40}\text{Ar}^*$ is the amount of radiogenic daughter isotope in the standard, and $^{39}\text{Ar}_K$ is the amount of ^{39}Ar derived from ^{39}K during irradiation. J depends on the duration of the irradiation, the production efficiency of ^{39}Ar from ^{39}K , and the branching ratio. The J value of the sample is determined by interpolation using the J values of the standards positioned around the sample during irradiation, and eqn [2] can now be rewritten as

$$t = (1/\lambda) \times \ln [J \times ^{40}\text{Ar}^* / ^{39}\text{Ar}_K + 1] \quad [4]$$

where t is the age of the unknown, J is derived from measurement of the $^{40}\text{Ar}^* / ^{39}\text{Ar}_K$ ratio of the standards, and $^{40}\text{Ar}^* / ^{39}\text{Ar}_K$ represents the parent/daughter isotope ratio of the unknown and is measured on a noble-gas mass spectrometer.

Some additional corrections are required. These corrections are graphically represented in Figure 1. For both K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods, the measured ^{40}Ar intensity needs to be corrected for the nonradiogenic ^{40}Ar component derived from air argon. This correction is very important in Quaternary samples, since the enrichment in radiogenic ^{40}Ar is often relatively low. The correction is generally performed by multiplying the ^{36}Ar intensity by the $^{40}\text{Ar}/^{36}\text{Ar}$ air atmospheric ratio (296, Nier, 1950; 298.7 Lee et al., 2006) and subtracting this value from the ^{40}Ar signal. Unnoticed and/or uncorrected isobaric interferences on the ^{36}Ar beam and the recent discussion on the true value of the $^{40}\text{Ar}/^{36}\text{Ar}_{\text{air}}$ atmospheric ratio (Lee et al., 2006; Valkiers et al., 2010) need to be addressed for precise and accurate application of the $^{40}\text{Ar}/^{39}\text{Ar}$ dating technique in the Quaternary. For the $^{40}\text{Ar}/^{39}\text{Ar}$ method, additional corrections need to be applied for the production of undesired isotopes of argon from K, Ca, and Cl isotopes during neutron activation (Figure 1). Production factors are commonly derived by measuring the isotope ratios of pure K, Ca, and Cl phases such as pure CaF_2 , K_2SO_4 , synthetic anorthite, and K-feldspar glass. The

correction factors for interfering isotopes of Ca tend to be quite stable in most reactors, but the correction factor for the production of ^{40}Ar from ^{40}K during neutron irradiation is more dependent on the fast to thermal neutron ratio and may vary between individual irradiations. Therefore this correction factor needs to be monitored more frequently.

Strengths and Weaknesses

One of the main strengths of the method lies in the abundance of ^{40}K in nature: because this abundance is quite high when compared to other naturally occurring radioactive isotopes, it is possible to apply the K/Ar method over much of the Quaternary. For minerals and rocks high in potassium, the detection limit lies well below 50 000 a, and specialist laboratories are able to reliably measure materials in the 1000–10 000 a range (Quideleur et al., 2001; Renne et al., 1997; Wijbrans et al., 2011), potentially opening the way for intercalibration with ^{14}C , U-series, and optically stimulated fluorescence dating techniques.

The strongest point of the conventional K/Ar method is its relative simplicity and rapid turnaround time, which has made it one of the standard methods for industry contract work. The most significant weakness of the K/Ar technique is that it relies on measurement of an absolute amount of ^{40}Ar that needs to be extracted quantitatively from a rock sample by melting a carefully weighed amount of rock or mineral fragments in a vacuum extraction system. Rock fragments of common basalt need to be carefully screened for alteration, altered glass, and phenocrysts of plagioclase, pyroxenes, and olivine. While alteration removes radiogenic argon, phenocryst phases commonly have significant amounts of extraneous (excess or

inherited) ^{40}Ar . Both effects will lead to biased results, which are often difficult to quantify with the K/Ar method.

The strong points of the $^{40}\text{Ar}/^{39}\text{Ar}$ method are that smaller amounts of sample can be measured more precisely and that, by applying the incremental heating technique, it allows for internal checks for ^{40}Ar inhomogeneity due to alteration, recoil loss of ^{39}Ar , or the presence in the sample of extraneous argon. The main drawback of the technique is the neutron activation step: it adds significantly to the per-sample analysis costs; the turnaround time is increased significantly; undesired neutron-produced argon isotopes interfere with the measurement of the $^{40}\text{Ar}^*/^{39}\text{Ar}_\text{K}$ ratio and have to be quantified; and finally the laboratory operation needs to be certified for handling radioactivity. Further, for absolute dating, the introduction of a mineral standard with known age introduces extra uncertainty. However, for most applications, the advantages of the $^{40}\text{Ar}/^{39}\text{Ar}$ technique outweigh the disadvantages.

New Perspectives

While researchers have used the K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ dating techniques with considerable success for many years now, at this moment a number of initiatives have the potential to substantially improve the reliability and the precision of the technique. Both the K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ techniques are routinely calibrated against mineral standards of accurately known age. Only a relatively few mineral standards (e.g., USGS biotite BS1, ANU biotite GA1550) have been calibrated absolutely against a carefully determined amount of air argon (Lanphere and Dalrymple, 2000; McDougall and Wellman, 2011). The ^{40}Ar contents of most other standards have been

Figure 2 Summary of published ages for the Quaternary Bishop Tuff ash fall. Ages are shown as published in the original publication and not recalculated to currently accepted decay constants or in case of $^{40}\text{Ar}/^{39}\text{Ar}$ dates currently accepted standard ages. Width of the bar represents 2 sigma uncertainty of the determination by Rivera et al. (2011). Data are from Evernden et al. (1957), Evernden et al. (1964), Dalrymple et al. (1965), Huber and Rinehart (1967), Hildreth (1977), Mankinen and Dalrymple (1979), Izett et al. (1988), Hurford and Hammerschmidt (1985), Pringle et al. (1992), Izett and Obradovich (1992), Bogaard and Schirnick (1994), Lueddecke (1998), Sarna-Wojcicki et al. (2000), Rivera et al., 2011, and Crowley et al. (2007).

determined by intercalibration against such 'primary' standards (Fish Canyon sanidine (FCs), Taylor Creek Rhyolite sanidine (TCR, TCR2), Drachenfels sanidine (DRA), Alder Creek, and biotites USGS standard biotite (SB3), Mount Dromedary biotite (MD-2) as examples). Although there is no reason to question the fundamental validity of these calibrations, they were carried out in the 1960s and 1970s and are still generally accepted without considering subsequent improvements in analytical protocols. As a consequence, the accuracies of the $^{40}\text{Ar}^*$ content determinations are substantially larger than the current analytical precisions with which we can determine the K/Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ ages ($\sim 2.0\%$ accuracy against $\sim 0.1\text{--}0.5\%$ analytical precision in favorable cases). Recently, a new initiative was started to accurately determine the absolute $^{40}\text{Ar}^*$ content of mineral standards against a carefully determined absolute amount of pure ^{40}Ar , providing a new metrologically sound basis for the techniques (Morgan et al., 2011). Parallel to this effort, common K/Ar standards have been accurately calibrated against tephra sanidine for which the age of extrusion was determined from the astronomical age of the cyclically bedded sediments into which the tephra was deposited (Kuiper et al., 2008; Rivera et al., 2011), and independent U/Pb data for selected tephra horizons have confirmed this result (Crowley et al., 2007; Wotzlaw et al., 2010). These initiatives combined will help to much improve the accuracy of the technique.

A second exciting prospect is in the development of new instrumentation. During the last 60 years, isotopic determinations were mainly carried out in the single-collector (Faraday cup, or SEM) mode or in some cases dual-collector mode, where the larger signals were measured on a Faraday collector channel and the smaller beams on an SEM. Recently, new mass spectrometer designs have become available with several SEM channels (Nu Instruments Noblesse, ThermoFisher Helix MC) or Faraday collector channels (ThermoFisher Argus-VI). These new instruments will combine faster data acquisition and improved sensitivity, resolution, and analytical precision because individual ion beams will be measured for longer time intervals. Several groups are working on testing data acquisition protocols that will fully exploit these intrinsic improvements (Coble et al., 2011; Jicha et al., 2010; Mark et al., 2009). As already mentioned, enrichment in radiogenic ^{40}Ar in Quaternary minerals is extremely small and its accurate determination relies on precise determination of $^{36}\text{Ar}_{\text{air}}$. Thus, a significant source of error, namely analytical uncertainty and bias, lies in the precision with which we can measure ^{36}Ar . With some of the new multi-collector instruments, the resolution on mass 36 is good enough to partially resolve molecular isobaric interferences such as $^1\text{H}^{35}\text{Cl}$ and $^{12}\text{C}_3$ from ^{36}Ar , and thus derive a better and more accurate determination of the ^{36}Ar beam intensity on mass 36.

As an illustration of technical improvements dating Pleistocene samples, we have plotted ages obtained for the Bishop Tuff in Figure 2. The Bishop Tuff is the product of a great volcanic eruption near Bishop, Long Valley caldera, California, and serves as an important chronostratigraphic marker for correlation and age control in the Quaternary of western United States. This tuff was originally dated by radioisotopic methods in the early 1960s using conventional K/Ar, and a recent study (in 2011) is the first to apply a multicollector data acquisition $^{40}\text{Ar}/^{39}\text{Ar}$ approach to the Bishop Tuff (Rivera et al., 2011).

In summary, these technical developments hold a promise for improvements in dating the late Pleistocene and Holocene. The $^{40}\text{Ar}/^{39}\text{Ar}$ method will be a reliable geochronometer that can be used for dating a wide range of materials in the youngest part of the timescale when these new improvements all have been implemented and tested in the coming years.

Introduction

The main focus of paleoclimate research over the last 50 years has been temperature change reconstruction, driven by the dramatic results produced by ocean and ice-core research. Paleohydrological research in comparison has received significantly less attention. As a result, the range of proxy techniques available to the paleohydrologist is significantly less than that available to those interested in past temperature change. This situation is perplexing when one considers how much more important is water availability than temperature to the vast majority of the world's population. Over the past 10 years, this situation has begun to change, due in part to the needs of the modeling community, which increasingly requires hydrological data sets (e.g., precipitation, evaporation, and surface moisture status) for climate model development and validation.

Lake-level research represents a critical paleohydrological archive. Throughout the Quaternary period, lakes have

fluctuated in size in response to climatically induced changes in hydrological balance over the lake–catchment system. The ubiquity of lake basins across the globe provides researchers with an opportunity to study paleohydrological data over a wide variety of spatial (local–continental–hemispheric) and temporal (10^1 – 10^6 years) scales. This spatial dimension is particularly important as the ability to distinguish patterns of lake-level change at the continental scale represents a starting point for elucidating the mechanisms of climate change (e.g., [Steffen et al., 2003](#)).

The roots of lake-level research probably lie in the investigation of the vast pluvial lakes that used to intermittently dominate the landscape of southwest United States, intertropical Africa, and Australia throughout the Quaternary. The existence of these ‘prehistoric’ lakes has been well documented for over a century. In Australia, detailed surveying recorded the full extent of Lake Eyre by the 1870s. In the 1840s, in southwest United States, G. K. Gilbert of the USGS began work on a

Figure 1 Comparison of the distribution of data points for (a) the first global lake status database published in 1979 and (b) the more recent situation in 1999. In 30 years, the database has quadrupled in size and continues to grow (GSLDB, 1999; Street and Grove, 1979).

sequence of ancient lake sediments deposited across northwest Utah, northwest Nevada, and southeast Idaho. In his final report to the USGS in 1890, he accurately calculated the area (20 000 square miles) and depth (1000 ft) of the ancient lake, the dramatic lowering through catastrophic flood, and also determined that crustal rebound must have been responsible for the elevated shorelines he observed. He named the site Lake Bonneville after an earlier explorer in the region. In 1949, Ernst Antevs was among the first to suggest that pluvial phases in the Great Basin lakes of southwest United States were linked to the presence of continental ice sheets over North America. It was not until the late 1970s, however, that the connection between pluvial and interpluvial phases was linked to Quaternary glacial cycles.

Advances in ^{14}C dating and drilling technology in the 1960s and 1970s saw an increase in lake-level studies, and slowly, a continental picture of events began to emerge. The first synthesis of continental data was produced for Africa in the late 1970s by Street and Grove (1976), followed 3 years later by the publication of the first global synthesis of lake-level data (Street and Grove, 1979). Data from 141 closed basin records spanning the period 1958–79 were collated and synthesized and a series of global maps were produced, which provided the first global overview of changing lake status for the last 30 ka. For the first time, it was possible to see how climate change occurred on the global scale.

Though the original 1979 paper was pitched as a ‘global’ synthesis, this title was somewhat misleading as data for large parts of the globe were missing (Figure 1(a)). In the case of

Russia and China, this was due to political reasons, but for much of the mid- and high latitudes the dominance of open lake systems posed a problem. Such problems were soon overcome with the development of new methods for open lake-level reconstruction such as the ‘Digerfeldt technique’ outlined below. The global database continued to expand and develop, culminating in the global lake status database (GSLDB; e.g., Kohfeld and Harrison, 2000), with a resource of over 600 sites spread across the globe (Figure 1(b)). Detailed continental scale syntheses are now available for most parts of the globe. There has been a marked improvement in temporal resolution as well, highlighted by the recent publication of the first high-resolution study of lake-level variation in west-central Europe (e.g., Magny et al., 2004; Figure 2). By combining the lake-level data with pollen, they were able to quantitatively reconstruct various climatic parameters, including mean annual temperature and annual precipitation, for the Holocene.

Next, we present an overview of the approach to lake-level reconstruction, focusing on the various sedimentary archives and reconstructive techniques that can be used in such studies.

Reconstructing Past Lake-Level Change

Background

The use of past records of lake level as a proxy for paleohydrological change is based on the close relationship that exists between lake volume/area and the balance of precipitation:

Figure 2 High-resolution Holocene lake-level record for the Jura mountains, the northern French pre-Alps, and the Swiss Plateau by Magny (2004). The vertical scales represent the number of dates for successive 50-year intervals between 12.25 and 0 cal ka BP.

evaporation ($P-E$) across a catchment. In closed (endorheic) 'nonoverflowing' lakes, particularly in semiarid regions, lake area represents the equilibrium between runoff from the catchment and the water deficit over the lake. This can be summarized in the following equation:

$$P + R + G_1 = E + O + G_0 \pm \Delta S$$

where P is direct precipitation onto the lake surface, R is catchment runoff, G_1 is groundwater input, E is evaporitic loss from the lake surface, O is surface outflow, G_0 is groundwater outflow, and ΔS is the change in storage (Street-Perrott

and Harrison, 1985). The situation is more complex with respect to open (exorheic) systems, which have a permanent inflow/outflow and tend to occur in regions where runoff dominates. Under such circumstances, a positive change in water balance may simply result in increased discharge at the outflow. Open systems are therefore likely to be much more insensitive to hydrological change, particularly over shorter time periods. Nevertheless, relict high shorelines around currently overflowing lakes in temperate regions suggest that increased discharge at the outflow is not always sufficient to compensate for changes in water balance (Harrison et al., 1991).

Figure 3 (a) Satellite image of the Lake Erhai catchment, northern Yunnan. The lake is bordered to the West by the Dali Plain (A), which is composed of old lake sediment deposited during an early Pleistocene highstand phase. The lake is tectonic in origin and the basin is currently subsiding in relation to the Diangchang Mountains, which abut the Dali Plain. The north of the lake is dominated by the Miju Delta (B), testament to the rapid infilling of the lake due to the high rates of erosion in the catchment. A selection of smaller lakes are scattered across the northern catchment, being further evidence of the previous highstand (C). Two former lake basins can be observed to the south of Erhai (D); both of these have been drained for agricultural land. (b) Xierhe river/rock bar looking upstream to Xiaguan and Erhai. The original outflow relates to a period of high lake level during the early Pleistocene. The present outflow is man made – another example of anthropogenic modification of the catchment hydrology. (c) Ceramic irrigation pipes and a decorative plate showing wet field irrigation; both are found in the catchment. Dating to the early Han dynasty (206 BCE–CE 220), they illustrate that even at this early stage a well-organized extensive wet field irrigation system was established in the catchment, drawing much of its water from the lake and the 18 streams which feed of the mountains. (d) Map of the Dali plain sent to the British Government by an envoy of the Muslim Suliman ca. 1871. The Miju Delta, a prominent feature of the modern lake, is conspicuous by its absence, suggesting it as a very recent phenomenon. A detailed environmental history of the Erhai catchment can be found in [Elvin et al. \(2002\)](#).

Long-term changes in 'lake status' (lake level, area, and depth) will affect a range of physical and biological processes in a lake and so can be reconstructed from geomorphic and lithostratigraphic records ([Harrison and Digerfeldt, 1993](#); [Street-Perrott and Harrison, 1985](#)). Water-level fluctuations affect space and habitat availability, the extent of the photic zone (the zone below the surface which allows enough light penetration in order for

photosynthesis to take place), water chemistry, stratification, and mixing regimes. In shallow lakes, falling lake levels may prevent thermal stratification and increase salt concentrations, in turn forcing a change in lake pH. Turbulence may also increase, leading to the reworking of exposed marginal sediments into the lake.

Disentangling and interpreting the complex set of processes that led to the preservation of a climatic signature within a

sediment record is a complex process. Such complexity arises from the fact that 'signals' preserved within the sedimentary record could be the result of a variety of internal and external factors unrelated to climate-driven changes in water balance. Significant changes in lake level can be triggered by a variety of nonclimatic factors, including natural infilling, land cover change, stream channel development, and anthropogenic activity. If an accurate interpretation of a sedimentary record is to be achieved, a clear understanding of the hydrological and sedimentological process at work across in the lake–catchment system is critical. A working knowledge of the geological history of an area is particularly important, especially in tectonically active areas. Tectonic/neotectonic processes are a relatively common cause of lake-level change, either directly through subsidence/uplift or indirectly through earthquake-induced rockfalls.

For Holocene-based studies, an understanding of past anthropogenic activity is critical, particularly in areas where there has been a long history of land-use change and modification. [Figure 3\(a\)–3\(d\)](#) highlights the potential role tectonic and human activity have played in influencing past lake levels at Erhai Lake, Yunnan province, China, and in doing so reinforces the importance of undertaking a detailed site survey prior to sampling.

Site Selection

For any given region, it is likely that only a small percentage of lake–catchment systems will be suitable targets for lake-level research. The ideal site will be the one that strikes the right balance between 'sensitivity,' 'longevity,' and the 'temporal resolution' of the sedimentary record. The approach taken will be largely dependent on whether one is dealing with a 'freshwater' or a 'saline' lake system as the marked differences that exist between their hydrological and sedimentological processes often warrant a very different approach to reconstruction.

The vast majority of freshwater lakes are located in the 'mid–high latitudes' where evaporation rates are comparatively low and precipitation is high. Most of the lakes in these regions are open systems, which may be much less sensitive to hydrological change than closed systems, but are less likely to suffer from desiccation, therefore increasing the chances of obtaining a complete sedimentary record. The sedimentary record for most of these lakes tends to be clastic dominated and comparatively organic rich. Freshwater carbonates are also common in karstic areas.

Most mid–high-latitude lakes are glacial in origin, and as such the sediment record normally only extends back to the last Pleistocene glaciation. Comparatively high rates of sedimentation, particularly in the mid-latitudes, can provide an excellent temporal resolution for this period. As one moves into the higher latitudes, sedimentation rates tend to decline, the colder climate and seasonal ice cover limiting biological activity and hence autochthonous sedimentation ([Lamoueux and Gilbert, 2004](#)). A number of freshwater sequences that extend beyond 18 ka, such as the European Maar lake sequences, which typically extend back to 100 ka, have been identified. Significantly older sedimentary records can be found in some of the world's greatest lakes, such as Lake Titicaca, formed ~2 Ma, and Lake Baikal, which is thought to

be the world's oldest lake with a sediment record thought to extend over the last 7 My.

In comparison, saline lakes are mainly found in the sub-humid, semiarid/arid regions (e.g., North American Great Plains, southeast Australia, and Africa) and at altitudes (e.g., Qinghai–Tibetan plateau and Altiplano of South America) where evaporation rates are high and precipitation is infrequent or very strongly seasonal. Most saline lakes are located in fault-bounded, 'closed' basins. Seasonal changes in precipitation often result in dramatic shifts in lake status between enlarged perennial lakes (wet) and playa deflation basins (dry). Consequently, the sedimentary record is often quite complex, consisting of a mix of evaporites, geochemical precipitates, catchment-derived clastic material, and eolian deposits.

Located in unglaciated areas, many saline lakes have the potential to provide long sedimentary records stretching back through the last glacial–interglacial cycle and beyond. Such long-core records reveal a paleohydrological record for the Quaternary characterized by repeated phases of lake contraction and expansion, reflecting their sensitivity to global climate change events. Owing to the unique hydrological and sedimentary processes that characterize saline-lake systems, they are widely regarded as the most sensitive of sites for paleohydrological research (e.g., [Street-Perrott and Harrison, 1985](#)). Unfortunately, owing to the high rates of evaporation and limited precipitation, saline lakes are comparatively rare.

Site Survey

For sites with an extant lake, a site survey should begin with an assessment of the basin topography, either manually using a weight and line or, if available, a digital echo-sounder. Shallow-sided basins are the preferred choice, as any change in lake level will be accompanied by a much more significant shift in surface area than that in a steeper sided basin. Slumping of marginal sediments is also much more problematic in steep-sided basins, particularly in tectonically active areas where earthquakes are common.

If possible, a subsurface survey of the sedimentary deposits should be undertaken and a variety of seismic reflection/acoustic profiling techniques can be used depending on the size of the lake basin under investigation and the required balance between resolution and penetration can be determined by the nature of the project. Though the equipment is expensive and often unwieldy, it can provide a detailed picture of the subsurface stratigraphy. Such information can be used to help characterize the depositional process at work (e.g., sediment focusing and faulting), which can then be used to identify the best coring site. If access to such equipment is not possible, a good estimate of depositional trends can be gained through the application of wave theory. All that is required is an understanding of basin hydrology and local meteorological conditions, particularly wind speed and direction ([Dearing, 1997](#)).

A detailed limnological survey of the site should also be carried out to provide an insight into the hydrological and sedimentological processes at work in the basin. Sedimentary processes in the lake can be significantly altered by a variety of factors unrelated to water balance, including wind strength (frequency and exposure), gravity, and heat transfer, all of which would be expected to vary over time ([Dearing, 1997](#)).

A detailed overview of the current situation can therefore aid in future interpretation of the sediment record.

Techniques for Lake-Level Reconstruction

It is now well established that, when working with lake sediments, any interpretation of lake-level changes must be based on multiple and supporting lines of evidence (e.g., [Harrison and Digerfeldt, 1993](#)). The wide diversity of sites precludes the development of a single sampling protocol, and the choice of archives to be analyzed and techniques to be used will ultimately be site specific. The majority of lake-level studies are based on a combination of 'geomorphological' (catchment sediments) and 'lithological' (lacustrine sediments) archives, which can be analyzed using a combination of 'lithostratigraphic' and 'biostratigraphic' reconstructive techniques. A summary of the different approaches to lake-level reconstruction is presented below with reference to freshwater and saline lakes. The marked differences in origin, hydrology, and sedimentary processes within such lakes often require a very

different approach to lake-level reconstruction and as such serve as a useful way of highlighting the various approaches available.

Geomorphic Archives

Historically, fluctuations in lake level were first noted from the presence of abandoned shorelines formed during periods of lake highstands. As highlighted by [Smith and Street-Perrott](#)

Figure 4 Images of the closed basin lake Dangqiong Cuo, Tibetan Plateau, China. Clearly visible in the foreground in both (a) and (b) are a series of concentric arcuate shorelines, geomorphic evidence of former higher lake levels. In the far distance, again in both (a) and (b), are a series of long-abandoned shorelines or terraces that drape the lower parts of the surrounding mountains, evidence of much higher paleolake levels. Photographs from NIGL, China.

Figure 5 Altai Region, Siberia, current lake visible in far distance. (a) Roadside exposure of lacustrine sediments deposited during glacial highstand, with geomorphic evidence pointing toward catastrophic jökulhlaup causing drop in lake level. (b) Close-up of roadside varved sediments, a characteristic deposit of glacial lakes in the region. Photographs courtesy of Dr. Philipp Allen.

Figure 6 Satellite images of Lake Chad taken in 1972 and 2001 showing the reduction in lake level and the further exposure of dune fields in the northeast. The shoreline of Mega Lake Chad is clearly visible. The images are taken from *The African Lakes Atlas*, UNEP, 2005.

(1983) and Sack (2001), landforms are broadly represented by the deposition of sediment or remnants of the erosion of sediment; therefore, geomorphology and sedimentology were key to early lake-level studies.

The interpretation of geomorphological evidence for changes in lake level is still as important as it ever was, but it is now universally augmented by the use of other lithological techniques discussed elsewhere in this article. The idea of a multiproxy approach to lake-level studies should not be

diminished; however, an understanding of the various geomorphic lines of evidence is needed in order to produce something of a baseline for further study. During the initial site investigation and mapping phase, geomorphic features should be identified. This stage may involve maps, aerial photographs, and remote/satellite imagery. The next stage would involve the detailed surveying of all features to a known datum so that altitudinal changes can be inferred. If applicable to the feature, sedimentological work and dating should also be carried out.

The geomorphology of a lake basin and especially the former shorelines is effectively a measure of the interaction between the water body and the landscape it is situated in. Sack (2001) provides an extended explanation of the use of shorelines and basin configuration for paleolimnological reconstruction. The presence or lack of an outflow in hydrographically open or closed lake basins, respectively, serves to control the geomorphological response to increased or decreased water input to the system. Open basin lakes respond to increases in water input by varying discharge via flow velocity and outflow width, whereas closed basin lakes express changes in input as alterations in lake-level and surface-area fluctuations. The result of this is that closed basin lakes tend to preserve fluctuations in lake level in the form of discrete shorelines (Figure 4(a) and 4(b)), whereas open basin systems are less likely to produce such identifiable geomorphological features. The catastrophic draining of a lake, possibly as a Jökulhlaup, often leaves behind remnant features such as stranded clifflines, shorelines, and raised lake sediments (Figure 5(a) and 5(b)). Places where modern lake levels are low enough, the exposure of other geomorphological features may also occur. The Chad Basin, North Africa, is a well-documented example of large-scale lake-level change (Grove and Warren, 1968). The basin now contains extensive dune systems within the shoreline of the former 'Mega Lake Chad.' Modern satellite imagery of Lake Chad shows the increased reduction in the extent of the lake and clearly highlights the dune fields present within the modern lake basin (Figure 6(a) and 6(b)).

In general, geomorphic features are discontinuous in terms of the entire perimeter of a lake. The mapping of paleoshorelines rarely allows entire lake levels to be reconstructed. However, with the introduction of digital elevation models and their incorporation into a GIS, shorelines can be extrapolated and 'fit' to existing maps. An example of this is shown by DeVogel et al. (2004) who combined the mapping and surveying of Lake Eyre, central Australia, with a digital elevation model, which in turn was used to produce a number of maps of the paleolevels of the entire lake basin (Figure 7).

Lithological Archives

Freshwater clastic lake sediments

The use of lake sediments from open freshwater lake systems for lake-level reconstruction has always been somewhat controversial. Dearing and Foster (1986), for example, consider that the level of a lake with a permanent inflow is unlikely to respond to climatic changes except for a change in the rate of discharge at the outflow. Owing to a paucity of targeted lake-level studies, many of the early open lake submissions to the GLSDB were reinterpretations of published data. Very few of these studies were targeted lake-level reconstructions, the vast

Figure 7 Maps depicting the outline of Lake Eyre at known paleolevels. The modern playas are outlined in black with the paleolake shown in blue. At the peak highstand in 125 ka (stage 5e), Lake Eyre would have covered a total area of $\sim 34\,000\text{ km}^2$, holding up to 430 km^3 of water. Reproduced from DeVogel SB, Magee JW, Manley WF, and Miller GH (2004) A GIS-based reconstruction of late Quaternary paleohydrology: Lake Eyre, arid central Australia. *Palaeogeography, Palaeoclimatology, Palaeoecology* 204: 1–13.

majority being pollen-based paleoenvironmental studies. The situation was further compounded by the fact that very little information was available regarding catchment hydrology and sedimentation processes. With runoff being a dominant factor controlling lake level, a detailed understanding of catchment hydrology and sedimentary processes is critical.

The situation improved significantly in the early 1980s with the development of a new technique for lake-level reconstruction designed by Gunnar Digerfeldt, specifically for use on open lake systems (Figure 8; Digerfeldt, 1986, 1988). The key

to the ‘Digerfeldt’ approach lay in the fact that it combined three main lines of stratigraphic data: (1) changes in the sediment limit, (2) sediment composition and type, and (3) distribution of littoral vegetation.

During a period of stable lake level, a ‘sediment limit’ will be established, above which fine sediment and organic matter cannot accumulate due to wind and wave action. Above this limit, the sediment record tends to be dominated by coarse sediments ($>0.125\text{ mm}$). A future drop in lake level should result in the establishment of a new sediment limit, the

Figure 8 Diagrammatic representation of the lake-level reconstruction approach of Digerfeldt (1986). The three temporal stages shown document the fall and then the subsequent rise in lake level, sedimentation, and the associated movement in the sediment limit (see main text for explanation). The effective movement of the sediment limit is preserved in the stratigraphic transect shown at the base of the diagram by the recorded presence or absence of coarse sandy gyttja/muddy sand which in turn corresponds to periods of low lake level or high lake level, respectively.

reworking of marginal sediments, and a hiatus of sedimentation in that area. This will be reflected in the sediment record by a coarsening of grain size lakeward. Any subsequent rise in lake level will reset the sediment limit to a higher position, with renewed sedimentation burying the coarse layers deposited during the preceding lowstand.

Changes in lake level will also have an effect on the spatial distribution of littoral macrophytes. Macrophyte distribution in lakes is primarily a function of light intensity and water depth. Under natural conditions, the littoral margins of a lake would typically be dominated by emergent macrophytes such as *Carex* and *Phragmites*. As one begins to move away from the littoral zone with the increasing water depth, the submerged/floating macrophytes such as *Potamogeton* and *Myriophyllum* increase in importance; they themselves are then replaced in the deeper sublittoral zone by low-light taxa (*Chara* and *Nitella*), which tend to dominate here (Cohen, 2003). Within the sediment record, an increase in lake level should therefore be reflected by an abrupt increase in aquatic taxa as the littoral zone expands, which will be countered by a decline in terrestrial macrofossils. As lake levels continue to rise, the more marginal taxa will be steadily replaced by deep-water taxa, and vice versa.

Macrofossil analysis was already a well-established technique for lake-level reconstruction prior to Digerfeldt's work but was normally applied to a single-cored sequence. This was most often taken from the center of the lake, away from the littoral zone where the vast majority of macrophytes lived. Determining whether an observed shift in the macrofossil record is climate driven or a response to catchment-based processes is very difficult from a single-cored sequence, due in part to a lack of repeatability and information on the nature of the sedimentary record (Hannon and Gaillard, 1997). Macrophyte distribution can be affected by a host of other factors including changing water chemistry or nutrient supply, turbidity, and competition. Significant changes in down-core macrophytes can occur as a result of hydrosere activity around a lake margin. Differentiating *in situ* macrofossils from inwashed material is also a problem, particularly in the shallows of high-energy lakes. By replicating macrofossil counts across multiple littoral cores, an accurate interpretation of the macrofossil record can be made.

The required data are collected from a transect of cores running from the margins toward the lake center (Figure 8). The distance between each core will vary from site to site but as a general rule the depth increase between adjoining cores

should not exceed 1 m. Core correlation is achieved through a combination of visual stratigraphy and lithological characteristics (particle size, mineral magnetic analysis, loss on ignition). The stratigraphic nature of the technique means that it can provide a quantitative picture of lake-level change, something that had never before been achieved. The correlated sequence is then dated using a palynostratigraphic framework, based on local pollen zones, supported by a sequence of targeted AMS ^{14}C dates.

A major advantage of the Digerfeldt approach is that it is broadly compatible with a whole range of other proxy techniques, particularly diatoms and chironomids, which are discussed next.

Diatoms

The use of diatoms for aquatic environmental reconstruction is well established. They are extremely sensitive to changes in certain environmental characteristics such as pH and salinity. They have lifestyles that are invariably planktonic (free floating), benthonic (pertaining to the water body bed), epiphytic (attached to plants), or perhaps tychoplanktonic (carried into the plankton from the benthos during periods of increased turbulence or water-column changes).

In terms of lake studies, the most obvious and clear diatom habitat changes would occur with isostatic uplift in a coastal area which would effectively 'isolate' a sedimentary basin, thus altering the once brackish water to freshwater over time. This

Figure 9 Carbonate lakes. (a) Theoretical model for a freshwater carbonate bench, highlighting zonal distribution of macrophytes (Cohen, 2004). Redrawn from [Murphy DH and Wilkinson BH \(1980\) *Sedimentology* 27: 123–135](#). (b) Morphological variation in carbonate precipitates sampled across the carbonate. Bar = 100 μm . In: Harrison SP, Frenzel B, Huckried U, and Weis M (eds.) *Palaeohydrology as Reflected in Lake-Level Changes as Climatic Evidence for Holocene Times*, *Paläoklimaforschung* 25, pp. 67–85. Stuttgart: Gustav Fischer Verlag. (c) Marginal carbonate bench stratigraphy for Hawes Water, northwest England. Spatial variation in the peat/marl contact reveals a detailed history of lake-level change at the site. An early phase of hydrosere encroachment (i) is followed by a period of rapid fluctuation (ii) and then a final phase of increasing levels (iii). The upper portion of the record has been lost through marginal peat cutting. (d) Down-core stratigraphy through carbonate bench spanning Late Glacial to mid-Holocene (Urswick Tarn, NW England).

salinity gradient is essentially 'missing' from freshwater lake systems (exceptions being closed basin lakes that encourage the concentration of mineral salts and therefore can exhibit saline and indeed hypersaline conditions), and instead the use of diatom life-form (ratios between deep-water benthos and shallow-water plankton) becomes a key to reconstructing former lake levels. A detailed review of the use of diatoms as indicators of water-level changes in freshwater lakes is given by Wolin and Duthie (1999), who identify a number of key lake sediment/diatom indicators that can and have been used, including life-form, turbulence, nutrient environment, and pH.

The majority of freshwater diatom studies make use of the changes in life-form, in particular the ratios between planktonic and nonplanktonic species. The association between open/deeper water and planktonic species and the links between low lake levels and the anticipated increase in macrophytes and therefore benthos and epiphytic species form the basis for diatom life-form studies. Bertzen (1987) and Lotter (1988) used life-form to reconstruct actual lake depths. The Digerfeldt (1986) method of lake-level reconstruction combined with diatom life-form is highlighted in Wolin (1996), where the signal from Lower Herring Lake, Michigan, showed that the transition period associated with both falling and rising lake levels was accompanied by an increase in benthic and epiphytic diatom species.

Chironomids and Cladocera

Chironomids and Cladocera are invertebrate remains that can be found preserved in most lake sediments and have both been used successfully as proxy methods for reconstructing paleoenvironments. Nonbiting midges (Insecta: Diptera: Chironomidae) have been used to study the effects of eutrophication and acidification and most significantly for paleotemperature reconstruction. Indeed, so promising is the use of chironomids for paleotemperature studies that they are likely to replace Coleoptera as the premier method for temperature reconstruction in temperate and arctic environments. Until recently, Cladocera have mainly been used for trophic and qualitative temperature reconstructions. A characteristic feature of both groups is that they occur in two distinct communities, shallow littoral and pelagic. Both groups have been used to reconstruct past lake levels but only in a qualitative manner. Korhola et al. (2000, 2005) have utilized these depth-species relationships to produce the first combined Cladocera/chironomid transfer function for quantitative lake-depth reconstruction. The transfer function is based on surface-sediment analysis from 53 lakes distributed across the northern Fennoscandian timberline. The transfer function appears to work well but has yet to be applied to other lakes.

Freshwater carbonate lake sediments

Carbonate sediments from small, hard-water lakes represent one of the most sensitive archives for midlatitude paleohydrological research. Carbonates are typically precipitated in the upper water column during the summer months, under the influence of the photosynthesis of both macro- and microphytes. Precipitation rates tend to be fastest in the littoral zone, where rates of biological productivity are highest. Over time, continued littoral deposition leads to the formation of a carbonate bench, which progrades lakeward. The autochthonous marginal nature of the carbonate bench deposits makes them exceptionally

sensitive to changes in lake level. The landward edge of a bench commonly supports a marginal fen peat complex, which typically encroaches lakeward in step with the prograding bench (Figure 9). Stratigraphically, the basal contact between the marginal peats and the carbonate sediments is very important as it defines the lake margin. Any subsequent change in lake level will be reflected by a lakeward/basinward displacement of this contact (Figure 9).

Following Digerfeldt's original method, spatial variation in the peat-carbonate contact can be traced using a series of cored transects. One of the advantages of working with carbonate lakes is that in the majority of cases the carbonate bench has become terrestrialized, making the process easier to execute. The correlated stratigraphic sequence can then be dated using a combination of pollen and ^{14}C AMS dates. Depending on the purity of the carbonate sediments, uranium-series dating may also be an option.

In a novel twist to the use of macrofossils, Magny (1998) has proposed a method that utilizes the morphology of calcite grains, the morphological characteristics of which mimic the macrophyte they were precipitated onto. If one can identify the range of calcite morphotypes associated with each macrophyte, it should be possible to use down-core variation in the type of calcite formations to reconstruct lake levels in the same way one would if one used aquatic macrofossils (Figure 9). Obviously, all the problems associated with macrofossil analysis are equally applicable to this technique. A site-specific survey of the relationship between macrophyte distribution and associated calcite morphotypes may help to alleviate at least some of the associated problems.

Most hard-water lakes are silica deficient due to the karstic nature of the catchment and the alkaline water chemistry. Consequently, diatom analysis is not always an option as the frustules are often simply redissolved into the water column at the end of the life cycle. Both chironomids and Cladocera are normally present in carbonate lake sediments, although the lake-level training set discussed above is yet to be applied to carbonate lakes.

Saline lakes

Over multimillennial timescales, down-core variation in the sediment record for the majority of saline lakes will be a reflection of long-term hydrological expansion and contraction in response to changing climatic conditions. During dry periods, when evaporation exceeds inflow, evaporitic concentration of the lake water occurs, increasing salinity, leading to the precipitation of evaporite minerals in the water column and on the lake floor. If the arid climatic conditions persist, desiccation will lead to the formation of a deflation basin and a break in the continuity of the sediment record. With the onset of a pluvial (wet) phase, the volume of the lake will increase with increasing inflow. Salinity will decrease and clastic sedimentation will increase in significance and previously deposited evaporites may be redissolved back into the water column. The exact nature of the sedimentary record is very site specific, and it is difficult to try and predict what one may find without a detailed knowledge of the hydrology and geochemistry of a site. A good example of the way in which climate can affect sedimentary processes in a saline lake is given by the depositional model for Lake Bogoria, Kenya, produced by Renaut and Tiercelin (1994) (Figure 10). Over shorter timescales, sedimentation will be influenced by a whole host of factors. Local differences in hydrology, topography, and

Figure 10 Theoretical model of sedimentation in Lake Bogoria, Kenya, highlighting the influence of climate change on sedimentary processes in saline-lake systems. Figure 11 Composite diagram from Great Salt Lake. The record was reconstructed using a wide range of reconstructive techniques. Redrawn from Balch DP, Cohen AS, Schnurrenberger DW, et al. (2005) Ecosystem and paleohydrological response to Quaternary climate change in the Bonneville Basin, Utah. *Palaeogeography, Palaeoclimatology, Palaeoecology* 221(1–2): 99–122.

limnological processes can cause significant spatial variation in water chemistry across a site, which will clearly have implications for sedimentation patterns across a basin and must be considered when interpreting the long-core record.

Core Recovery and Sediment Classification

The harsh environment conditions and the remote location of many saline lakes make fieldwork a difficult and expensive

proposition. Specialist drilling equipment is needed due to the depth of preserved sediment: >100 m is commonplace. The long duration of sedimentation has obvious implications for the integrity of the record. The older the sediment, the more likely it would have been altered by postdepositional processes such as diagenesis. Sampling resolution is often a serious issue in terms of defining the temporal resolution of the reconstructed record and also logistically with respect to sample numbers. Analyzing 100 m of sediment at a 1-cm resolution is clearly

impractical. Too coarse a resolution, however, and one could miss an entire interstadial!

Just as with freshwater lakes, a variety of reconstructive techniques are employed to characterize the sediment sequence in terms of 'lithofacies' and 'biofacies.' Lithofacies are normally defined on the basis of multiple lines of evidence, including TOC, TIC, X-ray diffraction, particle size, and mineral magnetics. Whereas in the past these analyses would have been carried out in the laboratory by an overworked post-doctoral student, the development of automated systems for data acquisition has made the whole process much less painful. Multisensor core loggers can now simultaneously run a whole suite of measurements (e.g., gamma-ray attenuation, magnetic susceptibility, and compressional wave velocity), while the cores are still intact. The process is rapid (up to 12 m h⁻¹) and more importantly nondestructive. Once the various lithofacies have been identified, a tentative environmental interpretation is then drawn up with reference to modern analogs and existing sediment classification schemes (e.g., Schnurrenberger et al., 2003). The down-core biofacies are then determined and a comparison is made with the lithostratigraphy. From this comparison, a composite stratigraphy is drawn up, which, once dated, will form the basis of the environmental interpretation. A recent study by Balch et al. (2005) on a 121-m core from Great Salt Lake, Utah, provides an excellent case study of how such studies should be undertaken (Figure 11).

Prior to the mid-1980s, ¹⁴C was the only viable dating option for saline-lake-sediment studies. Owing to a dearth of organic matter, chronologies were typically based on ¹⁴C-dated authigenic/biogenic carbonates. This approach was often problematic as contamination by 'old' carbon was difficult to prevent, further compounded by the increased mobility of CaCO₃ in arid conditions. As coring technology improved and deeper cores were recovered, the limited age range of ¹⁴C (45 ka BP) also became problematic. A variety of alternative dating techniques now exist that are more suited to saline-lake sediments. Radiometric techniques include U-series dating of authigenic and biogenic carbonates (e.g., Lin et al., 1998) and ⁴⁰Ar/³⁹Ar dating of K-bearing minerals (e.g., Trauth et al., 2003). Optical dating is now widely used on both lake and catchment sediments (e.g., Rich et al., 2003), whereas paleomagnetic secular variation has been employed successfully to date a number of sequences (Lund, 1996). Depending on the volcanic history of a region, tephrochronology is particularly useful not only as a dating technique but also for correlation purposes (e.g., Whitlock et al., 2000).

The vast majority of proxy techniques used to reconstruct past lake-level histories from freshwater sequences are also applicable to saline lakes, although the way they are interpreted will often be different. Therefore, only a brief overview of the techniques most relevant to saline sediments is presented here.

Oxygen-Isotope Analysis

Oxygen-isotope analysis ($\delta^{18}\text{O}$) provides a unique source of hydrological and paleohydrological data for saline-lake studies. Analyses can now be routinely measured on a variety of components found within the sediment record, including authigenic (e.g., marls and micritite) and biogenic (Ostracods and bivalves) carbonates, biogenic silica, and sulfates.

The stable isotope composition of saline-lake carbonates ($\delta^{18}\text{O}_{\text{Carbonate}}$) is primarily a reflection of the isotopic composition of the lake water at the point of precipitation. The isotopic composition of the lake water will in turn be a reflection of several interconnecting factors including atmospheric temperature and the hydrological balance of the lake catchment. During periods of increased evaporation and/or decreased precipitation, $\delta^{18}\text{O}_{\text{lake}}$ will become enriched in ¹⁸O as the lighter ¹⁶O is preferentially lost to the atmosphere. With the transition to a pluvial phase, increasing lake volume will result in a decrease in $\delta^{18}\text{O}_{\text{lake}}$ as the input of isotopically lighter water sources (atmospheric, groundwater, and fluvial) exceeds the loss of lighter isotopes through evaporation (Leng et al., 2005).

Significant fluctuations in $\delta^{18}\text{O}$ have been attributed to the changing balance between precipitation and evaporation at a number of closed sites in Africa (Gasse, 2000), southwest United States (Benson, 2004), and elsewhere. $\delta^{18}\text{O}_{\text{lake}}$ can be influenced by a wide range of factors and when one is working in a system that is prone to rapid and pronounced changes in hydrology, a detailed understanding of the modern hydrology is crucial. If possible, an overview of the isotopic systematics for the whole catchment should be produced. The $\delta^{13}\text{C}_{\text{TDIC}}$ record (measured in tandem with $\delta^{18}\text{O}$) is particularly useful under such circumstances as closed basin lakes commonly show covariation between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values for carbonates (e.g., Talbot, 1990). The complexities involved in disentangling the signal have to date precluded a quantitative interpretation of $\delta^{18}\text{O}$ data. Nevertheless, close parallels between long-core $\delta^{18}\text{O}$ records from saline-lake basins and global records of climate change such as ice-core records and SPECMAP illustrate the importance of this technique for paleohydrological research.

Ostrocods

Ostrocods are one of the most versatile fossils for paleoenvironmental research, particularly in saline systems. They are common to a wide variety of lakes and their robust nature means they are readily preserved. Their taxonomy and life history/ecology are well understood, and they have a long fossil record stretching back beyond the Quaternary. Analysis of down-core fossil assemblages provides a wealth of information on past limnology in the lake and changing climatic conditions (Griffiths and Holmes, 2000). Mourguiart and Carbonel (1994) have used quantitative changes in Ostracod assemblages to reconstruct paleolake levels in the Altiplano of Bolivia. $\delta^{18}\text{O}$ analysis of Ostracod shells for paleoclimate research is a well-established technique (Griffiths and Holmes, 2000). In most instances, it is also possible to examine the trace element composition of the valves; ratios of Mg/Ca and Sr/Ca have come under particular scrutiny as they are thought to be a proxy for salinity (Chivas et al., 1986).

Diatoms

In contrast to freshwater systems, the use of diatoms to reconstruct lake levels in saline lakes relies on the relative changes in conductivity from the concentration of salts due to fluctuations in moisture availability. Principally, deeper water is synonymous with reduced concentrations of mineral salts and therefore reduced conductivity.

Figure 12 Composite diagram of late Pleistocene–Holocene environmental changes at Eski Acigöl. Past lake status was estimated using a combination of diatom and $\delta^{18}\text{O}$ analysis. Reproduced from Roberts N, et al. (2001) *The Holocene* 11(6): 721–736.

In a closed basin, falling lake levels will cause a concentration of salts and therefore an increase in conductivity. This will be reflected in the diatom assemblage. Fluctuations in closed basin lakes have been shown by Reed et al. (2001) for the Laguna de Medina, Cádiz, Spain, where a complete Holocene lake-level change record is compared with North Atlantic Bond cycles (Bond et al., 1997) and the tropical African lake-level record summarized by Gasse (2000). A study from the closed basin lakes in the Konya Basin, Turkey, by Reed et al. (1999) compared stable isotope data with diatom data. It was stated that the diatom data provided the corroborative evidence needed for the interpretation of changes found in the oxygen-isotope ratios.

As with the freshwater lake equivalents, a fall in lake level would also be shown as changes in diatom life-form, with lower levels favoring benthonic and epiphytic species. Roberts et al. (2001) used a multiproxy approach to reconstructing lake levels in central Turkey. In addition, using diatom-inferred conductivity, diatom life-form was also utilized. The study allowed seven stages of lake level to be inferred from 1 (shallow, mesopolysaline) to 7 (deep, stratified, dilute; Figure 12).

Conclusions

The investigation of lake levels over time can be carried out in a number of different ways using a growing number of methods.

Historically, geomorphology and sedimentology formed the prime methodological tools for the reconstruction and inference of paleolake levels. Since the work of Gunnar Digerfeldt in the 1980s, developments in the use of lithostratigraphy to incorporate biostratigraphy, mineral magnetics, water chemistry, isotopic data, and a variety of different dating methods have increased to further both the resolution and the wholesale understanding of lake sedimentation and ultimately lake-level movements. The incorporation of transfer functions, statistical modeling, and GIS/DTM technology has allowed the subject to advance well beyond that imagined by the early scientists who chose to map the extent of ancient lake shorelines. As more pioneering studies emerge using new techniques, and as further studies adopt these techniques and refine them, the multiproxy approach to studying paleolake levels will undoubtedly get more and more accurate. As with any study, the planning stages are important, as they should outline what techniques are best suited to the basin being investigated and to what extent the project budget will allow these investigations to be performed. Without doubt, the use of a multiproxy approach utilizing mapping, surveying, sedimentology, biostratigraphy, and chemical analysis is the ideal, which should all aim to provide accurate data for the reconstruction of former lake levels; it is these studies that will help to increase the accuracy and depth of our understanding.

Introduction

Africa is one of the most arid continents under today's climate regime, yet it also contains many of the world's largest lakes. It spans the equator, and much of its land lies within the tropics, its extremities just extending to the warm temperate zones of both hemispheres ([Figure 1](#)). That many African lakes have changed size dramatically has long been appreciated ([North America](#)), and studies on African lakes can contribute significantly to our understanding of Quaternary climate dynamics in the lower latitudes ([Gasse, 2000](#); [Street and Grove, 1979](#)). Lakes are focal points within landscapes and ecosystems and, particularly in arid/semiarid regions, are centers of productivity and biodiversity. Reconstructions of dramatic changes in lake size and conditions, coupled with an understanding of current species distributions and genetic relationships, have recently provided biologists with new insights into evolutionary processes such as speciation (e.g., [Sturmbauer et al., 2001, 2003](#)). Lakes are key resources for human societies – evidence of the long story of human evolution is embedded in the deposits associated with East African lakes. Reconstructions of effective moisture over the past ~2 My in East Africa suggest that humid phases (which interrupted a Quaternary drying trend) may have been linked to key events in hominid evolution ([Trauth et al., 2005](#)). Throughout the Holocene, changes in society appear to have been linked to moisture changes reflected by lake dynamics (e.g., [Hoelzmann et al., 2001](#); [Verschuren et al., 2000](#)). The sources of the river Nile are collected in two great lakes, Tana and Victoria, which lie near the equator, and over many millennia the people of the Nile valley have monitored and responded to changes in its flow. Today, in many regions of Africa, water is a critical resource, and human populations have suffered under the impact of extended droughts, such as the Sahelian drought of the 1970s, 1980s, and 1990s and the drought affecting the Horn of Africa in the first decade of the twenty-first century. Concerns about detrimental changes in African moisture regimes in relation to global warming are increasing. In the light of paleolake data, fluctuations experienced in recent decades are less extreme than those experienced over the period from the LGM through the Holocene, but on the other hand, previous centuries have seen megadroughts far more intense than any experienced in the past 100 years ([Russell and Johnson, 2007](#); [Wolff et al., 2011](#)).

The focus of this article is on the tropics and the Sahara, where the most dramatic lake level changes are recorded. Key findings of lake studies over millennial and century time-scales are briefly reviewed. It is by no means comprehensive, and the reader is directed to the review of [Gasse \(2000\)](#) for tropical African paleohydrology; the volumes edited by [Johnson and Odada \(1996\)](#) and [Lehman \(1998\)](#) on East African lakes and [Gasse \(2002\)](#) on the Sahara-Sahel region provide more information. Few records extend back more than

one glacial–interglacial cycle, and many are intermittent. Most information is known for the period from the LGM to present. Millennial-scale changes in African lakes reflect the rhythms of orbital cycles and the status of sea surface temperatures in the Atlantic and Indian Oceans ([Barker and Gasse, 2003](#); [Gasse, 2000](#); [Liu et al., 2004](#)). However, the balance of forcing has changed with time. At the LGM and during deglaciation, events at high latitudes and a widespread drop in SSTs appear to have had a strong influence on African moisture levels. In the Holocene, in the absence of ice sheets and major thermohaline circulation (THC) fluctuations, orbital forcing has been predominant. Superimposed on long-term changes during the Holocene are more rapid, high-amplitude fluctuations that suggest another faster-acting control over moisture levels. Long-term and short-term variations in African lakes are addressed in the next two sections.

African Lake Dynamics and Millennial-Scale Climate Change

Africa's climate zones range from tropical–equatorial to Mediterranean. The equator bisects the continent, and seasonal shifts in the inter-tropical convergence zone (ITCZ) enhance the rains twice yearly in equatorial tropical zones. Further from the equator, the rains occur once a year in a monsoonal pattern ([Figure 2](#)); monsoon strength depends in part upon summer insolation values ([Liu et al., 2004](#); [Data-Model Comparisons](#)). The Indian Ocean monsoon strongly affects much of East Africa, and the West African monsoon brings moisture from the Atlantic to the Sahel zone south of the Sahara desert. A weaker monsoonal flow brings precipitation in the austral summer to areas south of the equator. In Southern Africa, cold near-shore waters in the Atlantic create an arid climate in the West, but warm Indian Ocean waters bring moist conditions to the East. In tropical East Africa, upwelling and cool sea surface temperatures along the western edge of the Indian Ocean suppress evaporation, making the Horn of Africa relatively arid, and the orography of the East African mountains and Ethiopian highlands adds further complexity to rainfall patterns.

Time series of isotopic variations and proxies such as diatoms, physical and chemical sediment properties of single cores and offshore transects, and geomorphological approaches such as mapping and dating of paleoshorlines have been successfully applied to obtain Late Quaternary records of changes in African lakes. Many lakes are carbonate systems, and consequently radiocarbon dating can be challenging; thus, chronologies may be imprecise ([Gasse, 2000](#)).

A Green Sahara

In Michael Ondaatje's novel 'The English Patient,' the protagonists find themselves deep in the Sahara Desert exploring a

place known as the Cave of Swimmers. On the cave walls are pictographs representing humans swimming in a lake surrounded by a landscape teeming with game. Archaeological evidence of human occupation earlier in the Holocene, including pictographs and charcoal hearths, has been reported from across the Saharan region (Neumann, 1989). Ancient drainages and lake basins, eroding subaerial lake sediments, and exhumed bones of crocodiles provide evidence that large regions of the now hyperarid Sahara were once moister and the semidesert regions to the south supported productive savanna vegetation (e.g., de Smet, 1998; Gasse, 2002). The vast changes recorded in the Chad basin (Leblanc et al., 2006; North America; Overview) and evidence of large lakes in other now dry basins underscore that over the Holocene, moisture regimes in Saharan and sub-Saharan Africa have fluctuated dramatically, together with landscapes and biota.

Figure 1 Map of Africa showing places mentioned in the text.

The early Holocene greening of the Sahara is largely attributable to Milankovitch orbital variations (**Astronomical Theory of Paleoclimates**). Today, moisture reaches the southern fringes of the Sahara via the monsoonal circulation (**Figure 2** (July/August)). The onshore flow is driven in part by heating of the continental interior during the boreal summer. Between 12 000 and 6000 ^{14}C years BP, Northern Hemisphere summer insolation values were greater than present, the continent heated more strongly, and a stronger onshore flow developed. The rains penetrated far further north, filling Lake Chad and other lake systems and greening the landscape.

The dynamics of the North African monsoon were investigated in an early data model comparison (**Data–Model Comparisons; Paleophytogeography**), which tested hypotheses about the causes of past climate change by comparing a paleoclimate model simulation with the observed proxy data (**COHMAP, 1988; Street-Perrott and Perrott, 1993**). This study was one of the first to use a large lake level database as a proxy record of continental-scale paleoclimate. At the Last Glacial Maximum (18 000 ^{14}C years BP), lake levels were extremely low. At 9000 and 6000 ^{14}C years BP, lakes were high, compared with the present (**Figure 3**). In the early Holocene simulation, stronger heating generated greater and more extensive precipitation. In contrast, the LGM was characterized by weak summer insolation, and this, coupled with a generally cooler and drier global climate, led to conditions at least as arid as those of today in the region.

A newer study by Lézine et al. (2011) makes use of over 1500 dated Holocene paleohydrological records from the Sahara and Sahel zones and new model simulations. The signal of maximum rainfall lagged the early Holocene summer insolation peak, and this is likely due to the effects of residual northern ice sheets and meltwater pulses to the North Atlantic, which in turn caused the ITCZ to shift southward, reducing precipitation. Furthermore, the signal for maximum open-water extent lagged precipitation, and this is interpreted to reflect the time required for aquifer recharge, which varied spatially, depending upon topography and groundwater hydrology; the interpretation is supported by the record from Lake Bosumtwi (**Figure 1**), which lies on the southern edge of

Figure 2 African monsoon circulation. Reproduced from Gasse F (2000) Hydrological changes in the African tropics since the Last Glacial Maximum. *Quaternary Science Reviews* 19: 189–211; Figure 3.

Figure 3 Graph shows the percent of lakes in one of three categories (low, intermediate, high) on a timescale of 18–0 ^{14}C ka. Modified after COHMAP members (1988) Climatic changes of the last 18 000 years: Observations and model simulations. *Science* 241: 1043–1052.

the Sahel zone in Ghana and has a lake level record that is thought to mirror local precipitation variation (Shanahan et al., 2006), and which leads the Saharan pattern.

The dramatic climate changes in the Saharan and Sahelian zones (Figure 1) during the Holocene are linked with prolonged human occupation of now arid regions. Hoelzmann et al. (2001) describe a sequence of cultures existing in association with a large paleolake basin in Western Nubia between 9400 and 3800 ^{14}C years BP and suggest that communication routes between the Nile valley and Lake Chad region existed during this time. Gasse (2002) also highlights the asynchrony of change and points out that the varied interactions of water and geology within the aquifers underlying these regions, plus differences in patterns of atmospheric deposition, led to variations in the chemistry of water bodies in both space and time. This in turn led to differing chemical composition of evaporate deposits associated with lakes. Certain deposits are preferred as a source of salt, and the ancient routes of salt caravans, still in use today, reflect this interaction of lake dynamics and geology (Gasse, 2002).

Late Quaternary Lake Dynamics in Eastern and Southern Africa

East Africa is a complex and dynamic region tectonically. The Great Rift Valley is the visible manifestation of a long-term process of continental rifting, whereby the easternmost portion of Africa is detaching from the rest of the continent. The region is characterized by earthquakes and volcanism, and the rift system is dotted with strings of lakes (Figure 1). The highest mountain complex in Africa borders the Rift Valley, adding complexity to the regional climate. The dynamics of East African lakes, particularly those within the rift, are thus affected by a complex set of climate factors, with tectonism a further

influence. Many of the Great Lakes are deep, subject to currents and turbidities, and have large sediment packages in their depocenters, meaning that drilling and core retrieval and interpretation are challenging.

Pre-Holocene records come from, among others, the Great Lakes Victoria, Tanganyika, and Malawi; Lakes Massoko and Rukwa, both south of the equator in Tanzania; and Lake Challa on the east slope of Mt. Kilimanjaro (Figure 1). Moernaut et al. (2010) use seismic-reflection data from a ~200-m sediment package from Lake Challa to interpret a lake level history over the last ~140 000 years (older ages based on an extrapolation of well-dated upper sediments). Low stands are linked to features identified as ponded basin sediments and high stands to units of draped lacustrine sediment. Greatest aridity, according to the age model, occurred during the period just prior to ~128 ka BP and between ~114 and ~97 ka BP; aridity was less extreme during the LGM. Several short periods of aridity identified in the record appear to match Heinrich events (Sub-Milankovitch (DO/Heinrich) Events), but otherwise much of the last glacial cycle was characterized by relatively stable and moist conditions. These data are supported by long records from Lake Malawi (Cohen et al., 2007; Scholz et al., 2011) that indicate severe aridity between 135 and ~70 ka BP; at these times, lake levels were far lower than during the LGM. After ~70 ka BP, sediment records from Lakes Malawi, Tanganyika, and Bosumtwi (equatorial West Africa, Figure 1) indicate that the period from ~70 ka BP until the LGM was relatively moist and stable across the continent, possibly due to a reduction of strong precessional influence in the orbital drivers of climate change (Scholz et al., 2011).

In contrast, at the LGM, as in the Sahara–Sahel region, records from many lakes in East Africa indicate low moisture levels (Barker and Gasse, 2003; Gasse, 2002). Lake Victoria was so low that at times it dried out, as demonstrated by seismic reflectors and subaerial soil horizons in cores (North America; Stager and Johnson, 2008; Stager et al., 2002; Talbot and Livingstone, 1989). In the Rift Valley, Lake Tanganyika was lower than today by at least 300 m (Gasse, 2002), and other rift lakes also record evidence of low stands (Figure 4; Felton et al., 2007; Gasse, 2000). Diatom data suggest that Lake Malawi was also at least as low as present during the LGM (Barker and Gasse, 2003). At Lake Rukwa, a 23 000-year record of terrestrial and aquatic vegetation indicates cool and dry conditions at the LGM (Vincens et al., 2005). At Lake Massoko (Barker et al., 2003), diatom-inferred lake levels are low at the LGM.

Relatively few lake records are available from further south in Africa, and records to date are somewhat equivocal (Gasse, 2000; Liu et al., 2004). A 200 000-year reconstruction of rainfall from the Pretoria Saltpan in Southern Africa (Partridge et al., 1997) records a cyclical pattern of rainfall that matches precessionally driven insolation variations that modulate the strength of the monsoon. However, rainfall is less well correlated with insolation over the past two cycles. In particular, the Pretoria Saltpan records dry conditions at the LGM, whereas orbital forcing would suggest an enhanced southern monsoonal effect. Dry conditions can be partly attributed to lower sea surface temperatures in tropical oceans, which led to significantly reduced evaporation and less moisture transport to the African continent thus reducing monsoonal effects (Gasse, 2000).

Figure 4 Late Quaternary records from the Great Lakes. Based on Barker P, Williamson D, Gasse F, and Gibert E (2003) Climatic and volcanic forcing revealed in a 50,000-year diatom record from Lake Massoko, Tanzania. *Quaternary Research* 60: 368–376; Gasse F (2000) Hydrological changes in the African tropics since the Last Glacial Maximum. *Quaternary Science Reviews* 19: 189–211; and Stager JC, Mayewski PA, and Meeker LD (2002) Cooling cycles, Heinrich event 1, and the desiccation of Lake Victoria. *Palaeogeography, Palaeoclimatology, Palaeoecology* 183: 169–178.

With the onset of deglaciation, lake levels generally rose (Figure 4), but rising trends were punctuated by regressions (see below). The detailed record from Lake Rukwa (Vincens et al., 2005) shows a deglacial warming, but indicators of a swamp environment at the coring locality suggest continuing low lake levels. The period ca. 12 000–5500 cal years BP saw low aquatic pollen totals, indicating a higher lake level. Subsequently, the return of swamp indicators shows lake level dropping and the return of more arid conditions. Relatively high Holocene levels are evident in lakes across East Africa as far as $\sim 7\text{--}8^\circ$ S, suggesting major trends in lake level largely reflect the patterns of ITCZ-driven precipitation in the equatorial and northern tropical regions.

Further south, evidence from Lake Malawi ($16\text{--}9^\circ$ S) from carbonate stratigraphy and diatoms in an offshore transect and from seismic studies (Finney and Johnson, 1991; Scholz and Finney, 1994; North America) suggests a moderate lowering of 100–150 m between 10 000 and 6000 years BP in an otherwise extended high stand extending from the Late Glacial. This is possibly the imprint of the Southern Hemisphere monsoon, which should have weakened in the Holocene (Liu et al., 2004; see below). The Holocene behavior of Malawi may reflect special subregional conditions related to its latitudinal span and its large and mountainous catchment. Further south, the Pretoria Saltpan records continuing low levels in the Holocene (Partridge et al., 1997).

Liu et al. (2004) modeled all the monsoon climates for the mid-Holocene and showed that insolation and ocean feedback are both important to the evolution of monsoon circulations. In particular, the mid-Holocene North African monsoon is enhanced by a reduction in upwelling and warmer sea surface temperatures north of the equator in the Atlantic. The Southern African monsoon weakens in response to lower austral summer insolation; the signal is reduced slightly in southernmost regions by warmer waters along the western coast of Southern

Africa. These results are broadly consistent with the lake level data, which indicate that the northern monsoon dominates even south of the equator. Further lake data from Southern Africa are needed to clarify the complex Late Quaternary forcing and response in this region.

High-Frequency (Centennial-Scale) Dynamics in African Lakes

Across the continent, millennial trends in lake level are punctuated by shorter events that are sometimes of considerable magnitude. With the onset of deglaciation, increases in moisture were not monotonic but pulsed, and arid intervals have punctuated the Holocene, even within generally wet periods such as the early and middle Holocene. Lake records from the late Holocene indicate that recent millennia have also seen severe episodes of drought, and these events can be related to the cultural record.

For the deglacial period, Gasse (2000) reports many lakes in equatorial Africa filling from as early as $>17\,000$ cal yr BP and certainly by 15 000 cal yr BP. Stager et al. (2002) dated desiccation events in Lake Victoria to $\sim 18\text{--}17\,000$ cal yr BP and some time between 15 900 and 14 200 years BP. These may be consistent with low stands in other lakes, although accurate dating of low stands is particularly problematic. A less severe low stand in Lake Victoria correlates with the Younger Dryas stage of the North Atlantic deglaciation ($\sim 12\,500\text{--}11\,500$ cal years BP). Arid events during the general trend to moister conditions in the Sahel and Sahara regions are also evident (Gasse, 2002; Street-Perrott and Perrott, 1990). Several authors have pointed out correlations between African lake behavior and events in, for example, the North Atlantic during deglaciation (Stager et al., 2002; Street-Perrott and Perrott, 1990). It appears that cooling of Atlantic SSTs, via glacial melt events and THC slowdown, for

example, affected large parts of the African continent, overriding regional controls over precipitation and evaporation, including the precessionally driven monsoon (see above). As in the full glacial, African moisture regimes remained sensitive to global-scale and ocean-driven events during the glacial–interglacial transition.

Such links can explain arid events into the early Holocene, but marked arid events are nevertheless recorded across large parts of the continent throughout Holocene. So far, this high-frequency variability over decades and centuries is not well understood, yet we need to understand it to plan for future climate change. There has been considerable discussion as to what the main forcing factors may be. For the Holocene, Lamb et al. (1995) recognize a synchronicity in the nature and timing of dry events in the warm temperate Atlas mountain region, which receives predominantly winter precipitation, with those in tropical Africa, where summer rains dominate, and they suggest the link may be cooler SSTs in the North Atlantic that could affect both monsoonal and westerly moisture levels.

Spectral analysis has been applied to high-resolution late Holocene records from several of the great lakes of East Africa. Over the past 4000 years, Lake Turkana (Kenya) laminated deposits show several submillennial periodicities, including 22, 18.6, and 11 years, which Halfman et al. (1994) have pointed out matches short-term solar variability (see [Volcanic and Solar Forcing](#)). A high-resolution record of calcite elemental composition and biogenic silica for the past 5400 years from Lake Edward, Uganda ([Russell and Johnson, 2005](#)), indicates century-scale droughts at ~4100, 2000, and 850 years BP and numerous lesser droughts. At Lake Edward, [Russell and Johnson \(2005\)](#) demonstrate marked fluctuations over past 1500 years, with three arid phases characterizing the majority of the period. The past two centuries have been unusually moist based on the whole period of record, but an extreme arid event is indicated between AD 1700 and 1800. [Bessemis et al. \(2008\)](#) report sedimentological evidence of a severe drought about 200 years ago from several shallow lakes, two

in Uganda and one in Kenya. A record from Naivasha ([Verschuren et al., 2000](#)) based on sedimentology, diatom assemblages, and fossil midge assemblages indicates drought for the period AD 1000–1270; wetter conditions followed, but these were punctuated by three more long dry events that appear more extreme than any twentieth century droughts (AD 1380 ± 1420 , 1560 ± 1620 , and 1760 ± 1840). Furthermore, records of precolonial history indicate alternating phases of famine, migration, and unrest on the one hand and periods of prosperity and stability on the other; the periods of unrest map almost exactly onto the drought periods in the Naivasha record ([Figure 5](#); [Verschuren et al., 2000](#)).

The coherence of the AD ~1750–1850 drought signal across Eastern Equatorial Africa suggests a major climate anomaly. However, while high stands occurred in the several centuries prior to the nineteenth century in Eastern Equatorial Africa, further south at Lake Malawi, levels were lower at this time ([Russell and Johnson, 2007](#)). This meridional difference does not seem explainable by an ITCZ shift, but it may reflect the position of the Congo Air Boundary, which marks a convergence zone between Atlantic and Indian Ocean air masses, and thus may represent a teleconnection to the ENSO ([Russell and Johnson, 2007](#)).

The role of ENSO in short-term variability is also invoked for the interannual scale in a study by [Wolff et al. \(2011\)](#). Currently, yearly precipitation in Eastern Equatorial Africa is partly influenced by ENSO, with rain/floods linked with El Niño and drought with La Niña years. At Lake Challa, dark-light varve couplets are formed from amorphous organic matter deposited in the moist season and diatom frustules that characterize the dry season, respectively; the latter control varve thickness. When varve thickness is compared with the past 150 years with ENSO index, thick varves occurred in La Niña years and thin ones in El Niño years. Thicker varves in LGM sediments relate to the generally drier climate then (see [Moernaut et al., 2010](#)), but interannual variability in varve thickness over the past 3000 years is greater than that in LGM; some varves

Figure 6 Bathymetric map of Lake Tanganyika.

exceed those of the LGM in thickness, suggesting years of extreme drought. If this association can be extrapolated to the future, warmer temperatures in Eastern Equatorial Africa may also be associated with higher interannual variability and hence extreme drought years.

Dating uncertainties still mean that the precise details of such short-term variability need further investigation. Even so, the general pattern shows droughts (that are likely regionally synchronous) superimposed onto a general late Holocene trend of increased aridity that reversed somewhat in the past two millennia. The conclusion is clear and somewhat daunting: century-scale droughts of great magnitude have occurred naturally under late Holocene conditions and we can assume they are likely to occur again, and intermittent extreme drought years are also likely. This is clearly of great concern, given the increasing pressures on water resources generally in East Africa (Russell and Johnson, 2005). Irrespective of the impact of future global warming, water management strategies should be flexible enough to cope with extended and/or droughts in the future.

Lake Level Change and Evolution: The Cichlid Fishes of African Lakes

Water level changes in the order of several hundred meters are recorded in great lakes such as Malawi and Tanganyika during the Late Quaternary, and Lake Victoria may have completely desiccated (see Section 'Late Quaternary Lake Dynamics in Eastern and Southern Africa'). Such large fluctuations in lake area and volume may have led to the temporary fragmentation of large lakes into several isolated basins and subsequent coalescence. Changes in the extent and continuity of habitats are

important factors driving evolution, as they offer potential environments for processes of speciation and radiation to occur; gene flow among subpopulations is prevented by intermittent barriers – in this case, changing lake levels.

The organisms in question are the highly diverse cichlid fishes. Molecular phylogenies have been developed for so-called species flocks in several of the great lakes (Verheyen et al., 1996; Sturmbauer et al., 2001, 2003). The mapping of genes across the populations shows evolutionary patterns developing in response to water level changes at two scales. For example, in Lake Tanganyika, three clades (ancestrally related groupings) map onto three sub-basins that during Quaternary low stands would have been isolated from each other (Figure 6; Verheyen et al., 1996). However, as the fish tend to inhabit shallow regions of the lakes, major increases in lake level also establish barriers to gene flow among populations by interposing stretches of deep water (Sturmbauer et al., 2003). Observed genetic patterns suggest that increases in lake level can lead to explosive radiations within isolated populations and that these often show parallelism in morphologies and adaptations. New genetic studies on populations of cichlid fish in shallow water areas of Lake Tanganyika show the dynamics of population shifts that underlie the speciation events. Reconstructed population histories largely match with known major lake level changes, with deeper splits occurring >100 ka BP and others during the LGM low stand ca. 20 ka BP (Koblmüller et al., 2011).

That Lake Victoria probably dried completely in the late Pleistocene suggests that the latest species flock became established and radiated extremely rapidly (Johnson et al., 1996; Stager and Johnson, 2008). With the advent of molecular phylogenetic techniques, the cichlid fish in African lakes promise to be a model system for investigating evolution in strongly fluctuating environments.

Asian Lake-Level Records

Lake level reflects water-volume changes in a lake and thus is a hydrological measure that changes largely in response to local water budget (precipitation–evaporation (P–E)) (Street-Perrott and Harrison, 1985). In Asia, lake-level changes have been sensitive to climate changes, particularly to extreme droughts in arid and semiarid catchments (e.g., lakes in the Aral and Tarim Basins), to widespread catchment flooding in coastal plains (e.g., the mid and lower reaches of Changjiang/Yangtze River), and to the development of saline waters on highlands (e.g., lakes of the Tibetan Plateau; Hu, 2001; Pan and Chen, 2010; Qin, 2008). Tracing long-term lake-level change aids scientific prediction of catchment floods and droughts, rational utilization of lake water resources, and protection of lake environments in Asia (Shen et al., 2010; Yu and Shen, 2009).

As no instrumental records date from pre-Industrial time, all long-term P–E reconstructions rely on geological lake-level records, with various indicators derived from studies of geomorphology, sedimentology, geochemistry, paleobiology, and archaeology of lakes (Harrison and Digerfeldt, 1993). Reconstructions of lake-level changes involve different timescales. Under the setting of tectonic subsidence, structurally controlled lakes can persist from one to ten million years: for example, Qinghai Lake, which has continuous lacustrine deposits dating from the Oligocene (Zheng et al., 1989). Many other lakes provide Holocene or late-Quaternary histories over many thousands of years. On the other hand, more ephemeral lakes formed by geomorphologic processes, such as ox-bows, lagoons (e.g., Xihu/West Lake in Eastern China), and proglacial lakes (e.g., Tianchi/Heaven Lake of Altai Mountains; Wang and Dou, 1998) normally only last hundreds to a few thousand years.

Dramatic lake-level changes on a late-Quaternary timescale have been recorded in Asian lakes with extreme characteristics, such as the Aral Sea and Qarhan Salt Lakes (Hu, 2001), the hypersaline Dead Sea and Aiding Lake, two of the lowest elevation lakes, and Sumuxi Co and Num Co (Zhu et al., 2003), two of the highest elevation lakes. Records of lake-level changes and syntheses of lake status from Asia have become an important tool for reconstructing paleoclimate at a continental to global scale (e.g., An et al., 2011; Harrison et al., 1996). Assessments of lake-level changes using a multiple-category scheme (very high, high, ..., very low, etc.) have provided a flexible coding basis to evaluate precipitation and P–E simulations in paleoclimate modeling (e.g., Qin et al., 1998; Yu et al., 2007). Lake-level databases (Street-Perrott et al., 1989; Tarasov et al., 1996; Yu et al., 2001a,b) hold about 150 lake-level records for Asia, ~54% with a recording length of the Holocene and 26% extending to 20 ka BP (Figure 1).

Historical Review of Asian Lake-Level Studies

From Closed to Overflowing Lakes

Investigations of Quaternary Asian lakes began early in the twentieth century. Some of these studies documented changes in lake level in response to climate changes (e.g., Hedin, 1922). With investigations of minerals or water resources, more lake-level studies were achieved up to the 1980s (e.g., Nanjing Institute of Geography and Limnology (NIGL), 1989; Zheng et al., 1989). Due to the assumption that overflowing lakes respond to changes in regional water budgets solely through changes in discharge (Dearing and Foster, 1986), most studies during this period were focused on closed lakes, for example, studies of the Dead Sea (Kaufman, 1971) and Qaidam Basin (Chen and Bowler, 1986). The recognition that overflowing lakes also respond to climate changes (e.g., Mason et al., 1994) has led to more Asian lake data being used to reconstruct past-regional climate changes, for example, Hulun Lake and Xingkai/Khanka Lake in Northeast China (Qiu et al., 1988; Wang et al., 1995), and Erhai and Fuxian Lake in Yunnan Plateau (NIGL, 1989). These studies mean that many Asian areas are well represented, and they extend study areas from closed basins that are mostly in the arid–semiarid interior into open basins that are mostly in the Asian monsoonal lowlands where overflowing lakes are dominant.

Basis of Lake-Level Reconstruction

Like studies in Europe and North America (Harrison and Digerfeldt, 1993), Asian lake-level reconstructions for most of the basins are based on changes in the nature of the sediments and sedimentary structures, as revealed in sediment cores, which can qualitatively reconstruct lake-level changes (NIGL, 1989; Zheng et al., 1989). Evidence of geomorphology, archaeology and historical records has been used to reconstruct the absolute levels and areas of lakes (Chen and Bowler, 1986; Pachur et al., 1995; Qiu et al., 1988). In arid–semiarid areas of Asia, changes in water salinity can also be used as an indicator of changes in relative water depth and hence lake-level status. Qualitative estimates of salinity (fresh, brackish, and saline) can be made based on sediment mineralogy and geochemistry. As the evaporative concentration of the lake water increases, there is a shift in the mineralogy/geochemistry of the sediments. The general sequence is from carbonate, borate, mirabilite, and nitrate to halite with increasing water salinity (Zheng et al., 1989). Paleoecological evidence, specifically changes in the species assemblages of aquatic plants, diatoms, and ostracodes, has been used to provide corroborating evidence for the reconstructed changes in water depth.

Figure 1 (a)–(f) Information on lake-level studies in Asia. (a) Database source: OLLDB (from [Street-Perrott et al., 1989](#)), CLSDB (from [Yu et al., 2001a,b](#)), FSUDB (from [Tarasov et al., 1996](#)), with lake hydrological type; (b) lake elevation in meters a.s.l.; (c) lake origin types; (d) and (e) lake record length (ka BP); (f) indication of numbers of ^{14}C dates in each lake study. Figure 1 (Continued)

Studies of the aquatic communities in modern Asian lakes provide the basis to infer water salinity from species assemblages. Such relationships of water salinity and depth ranges of ostracodes/diatoms are shown in [Figure 2\(a\)](#) and [2\(b\)](#), respectively.

Deep-Lake Drilling in Asia

Asia has deep-lake basins with thick lacustrine deposits that are ideal sites for exploring lake-level history and long-term climate change. Considerable progress has been made toward

reconstructing past climate in Asia, due in part to deep-lake drilling programs (e.g., [Baikal Drilling Project, 1997](#)). Deep-lake drilling has taken place in the Dead Sea, with a record back to 400 ka BP ([Stein et al., 2005](#)); Lake Baikal in Russia, which produced a 200 m-long core with a 150-ka BP record ([Oberhänsli and Mackay, 2005](#)); Lake Biwa in Japan, a 911 m-long core dating from 430 ka BP ([Takemura et al., 2000](#)); Cuoe Lake in China, a 197 m-long core with a 2800-ka BP record ([Shen et al., 2004](#)); and Heqing Paleolake in China, a 737 m-long core with a 2600-ka BP record ([Hu et al., 2005](#)).

The deep-drilling core from Heqing Paleolake on Yunnan Plateau, southwestern China, was sampled at 10–50 cm

intervals, with 900–2000-year resolution ([An et al., 2011](#)). The record, which covers 2.6 Ma, has demonstrated the importance of inter-hemispheric forcing in driving Indian summer monsoon (ISM) variability at the glacial–interglacial time scale. The Heqing ISM index, global ice volume of benthic $\delta^{18}\text{O}$, and the Antarctic deuterium record show a variable relationship of Heqing ISM minima with global ice-volume maxima during three intervals over the past 2.6 My. In the middle interval (1.82–0.92 Ma), most ISM minima are coincident with ice-volume maxima. In the younger (<0.92 Ma) interval, most ISM minima lead ice-volume maxima. In the older (2.60–1.82 Ma) record, half of ISM minima lead

Figure 2 (Continued)

ice-volume maxima. In contrast, interglacial ISM maxima are correlated with global ice volume minima and associated with an enhanced Indian low. These patterns suggest that feedbacks from ice sheet and ocean dynamics can modify effects of orbitally forced insolation (An et al., 2011). Such records can be compared with deep-sea drilling studies to describe long-term cycles of climate change in Asia and thus improve understanding of ocean-continent linkages, and the roles of orbital forcing and inter-hemispheric forcing in the Earth system.

From Individual Study to Regional Synthesis

The recognition that lake data could be used to reconstruct past regional climate changes led to the construction of the African lake-level database, and thus to a global database: the Oxford Lake Level Data Base (OLLSDB: Street-Perrott et al., 1989). However, the OLLDB only featured closed lake basins. The recognition that open lakes also showed climate-induced changes led to efforts to synthesize lake data for more overflow lakes than the close-basin lakes and areas: the European Lake Status Data Base, the Former Soviet Union and Mongolian Lake Status Data Base (FSUDB: Tarasov et al., 1996) and the Chinese Lake Status Data Base (CLSDB: Yu et al., 2001a,b) have now been established. As more individual Asian lake-level studies are carried out, it has become possible to synthesize regional lake-level changes and identify changing patterns at a continental scale (Fang, 1991; Farrera et al., 1999; Harrison et al., 1996; Shi et al., 2001). The changing patterns have been interpreted in terms of changes in interplay of the westerly and the Asian monsoons during the late Quaternary. These lake-level records and databases provide a systematic basis for mapping lake-level changes at a variety of spatial scales, identifying the patterns of hydrological and atmospheric circulation changes, and evaluating precipitation and P-E fields of paleoclimate simulations (see below).

From Reconstruction to Determining Causes of Lake-Level Change

Lake-level changes are controlled by two fundamental factors: lake-basin change and change in water input. Changes in lake-basin volume can, for example, result from tectonism, siltation/scouring, and changed river routes. Changes of water input reflect the discharge into the lake, which can be a direct consequence of climate change in the catchment: variation of strength and intensity of precipitation and/or variation in evaporation reflecting air temperature and humidity levels. Indirectly, climate influences land-surface conditions, which influence evapotranspiration and runoff.

Mapping modern lake status onto P-E shows that modern lake-level changes in China are mainly controlled by regional P-E (Figure 3(a)). Among 487 large natural lakes (surface area greater than 10 km²) there are 57.1% saline lakes and 42.9% freshwater lakes. Most freshwater lakes are found at the locations where there is a positive water balance ($P > E$) and mean annual precipitation is >600 mm. Where the water balance is negative ($P < E$) and mean annual precipitation is <600 mm, saline lakes dominate. Comparing this pattern with the modern lake-level status (0 ka BP) reconstructed from geological evidence, (Yu et al., 2001a) show lakes with high and

intermediate levels are mostly distributed in Southern China and those with low levels are in northern and northwestern China and the Tibetan Plateau (Figure 3(b)). The boundary line between the high-intermediate and the low lake-level regions is located at 35–30° N, virtually coincident with the 0-mm contour of annual P-E.

Nowadays, lake-level studies are not only focused on reconstructing processes and regional patterns but are also linked with paleoclimate modeling, which allows the exploration of mechanisms. Possible causes of Asian lake-level changes were studied through data and modeling comparisons (COHMAP Members, 1988; Qin et al., 1998; Yu et al., 2003). These studies have revealed that the lake-level changes are the results of different mechanisms at different scales: direct response to catchment P-E changes on a regional scale, consequence of changes in atmospheric circulations and land-surface conditions on subcontinental and continental scales, and fundamental changes in the global driving forces of climate: insolation, glaciation, and land-sea dynamics during the late Quaternary.

Overview of Regional Asian Lake-Level Changes Through the Late Quaternary

Based on lake-level databases of the OLLDB, FSUDB, and CLSDB, we can systematically view time sequences of Asian lake-level changes. For the convenience of presentation, the Asian region is divided into four subregions based on their geographical features: the Middle East (20–55° E and 10–50° N), Central Asia (55–104° E and 40–70° N), the Tibetan Plateau and surrounding area (70–104° E and 10–40° N), and East Asia (104–150° E and 20–70° N). For each subregion, six to eight lake-level curves in part (a) of Figure 4(a)–4(d) and histograms in part (b) of Figure 4(a)–4(d) are plotted, showing a general temporal sequence of the grouped lake behaviors.

Middle East

There are 30 lake-level records in the subregion with recording lengths from <10 ka BP to >30 ka BP (Figure 4(a)). High lake levels dominated (30–80%) before 17 ka BP, low lake levels dominated (70–20%) after 17 ka BP, suggesting a long-term trend toward drying from 30 to 0 ka BP (currently 70% of lakes are at low levels).

Central Asia

There are 34 lake records (Figure 4(b)). Four peaks of high lake levels occurred at 30–25, 17–15, 7–6, and 4–3 ka BP. Low lake levels (40–60%) occurred at the Last Glacial Maximum (LGM) and in the early Holocene (~ 8 ka BP).

Tibetan Plateau and Surrounding Areas

Forty-one lake-level records are registered for the Tibetan Plateau subregion (Figure 4(c)). Three periods of high lake levels occurred at 30–24, 22–20, and 8–5 ka BP, respectively, with each high stage less prominent, indicating a long-term trend

Figure 3 (a) and (b) Comparison of modern annual P-E and lake status (closed or overflowing) in China. (a) Contours of mean annual P-E (mm) where $P-E=0$ is shown by the dashed line. All 459 lakes plotted in the figure have surface areas greater than 10 km^2 . (b) Levels for 55 Chinese lakes at the present time (0 ka BP), where the boundary between low and high-intermediate lake status is indicated by the dashed line. Data sources from Wang and Dou (1998) and Yu et al. (2001b).

toward a more arid climate from 35 ka BP to the present. In fact, most modern lakes in the region are smaller now than at any time during the past 35 ka BP.

East Asia

There are 27 lake-level records (Figure 4(d)) from the east-Asian subregion. There are no records for the interval 23–18 ka BP. Evidence of sedimentary hiatuses or loess deposits suggests that this period was extremely arid and most lakes were dried

up. High lake levels occurred in the early and mid-Holocene (intermediate and high lake levels 95%).

Spatial Patterns of Asian Lake-Level Changes

Mapping of lake-level data makes it possible to identify patterns of hydrological and climatic change. Here, we introduce spatial patterns for three time slices (Figure 5), which represent key climate periods during the late Quaternary: the

mid-Holocene (~ 6 ka BP; e.g., [Qin et al., 1998](#)), the LGM (~ 18 ka BP in ^{14}C years or equivalent to 21 ka BP in calendar years; e.g., [Farrera et al., 1999](#)), and the late Marine Isotope Stage 3 (MIS-3) dated ~ 30 – 35 ka BP (e.g., [Shi et al., 2001](#)). The data sources are same as in section 'Historical Review of Asian Lake-Level Studies' above, and the climatic interpretations are based on the relevant literature.

Mid-Holocene

Reconstructed lake levels at 6 ka BP show conditions wetter than those of the present across much of the Asian continent, including the Russian Far East, northeastern north China, the Mongolian Plateau, the interior of Xinjiang, the Tibetan Plateau, the northern Indian mountains, and the Arabian Plateau. This wet belt was more than $\sim 10,000$ km long from east to west,

and $\sim 3,000$ km wide from north to south ([Figure 5\(a\)](#)). On both sides of this wet belt, lake levels were lower than the present, with a northern dry area surrounding the Caspian Sea, and the southern dry area in Southwestern and Southern China.

This pattern indicates a major change compared with the present. The key difference is the enhancement of Asian summer monsoon, forced by higher summer insolation that would have increased precipitation in South, Central and East Asia ([Kutzbach et al., 1998](#)). The melting of the last glacial ice sheets in the Northern Hemisphere resulted in northward-shifted and weakened Westerlies, leading to less precipitation over the eastern Mediterranean region ([Harrison et al., 1996](#)). The drying of southern China represented the northward and westward shift of the subtropical high-pressure system; conditions were dominated by offshore (land-sea) winds, low summer precipitation and high-annual aridity ([Qin et al., 1998](#)).

Figure 4 (a)–(d) Asian lake-level changes since 30 ka BP in four subregions. For each subregion there is a lake location map, a set of individual lake-level curve diagrams, and a histogram showing the numbers of lakes of high, intermediate, and low level through time. The lake locations are marked by circles; lakes coded as 1, 2, etc. have a matching lake-level curve. Vertical marks on the level curves (2, 1, 0, –1, –2) represent much higher, higher, no change, lower, much lower lake levels than today, respectively. Sources for histograms: OLLDB, FUSDB, and CLSDB. (a) Middle East; (b) Central Asia; (c) Tibetan Plateau and surrounding area; (d) East Asia.

(Continued)

LGM

Conditions drier than those of today characterized most areas east of 100° E, including the Yunnan Plateau, the Mongolian Plateau, the Eastern China Plains, and Taiwan. The extremely dry conditions meant that most lakes dried up; no lacustrine deposits have been found to date. Loess and mixed terrestrial deposits representing this period were found at Taihu Lake and Hulun Lake, where the modern water areas of these two lakes are 2428 and 2339 km², respectively (Yu et al., 2003). This pattern (Figure 5(b)) indicates that there was a stronger winter monsoon and weaker summer monsoon than present. This resulted from the dominance of a glacial anticyclone induced

by increased ice and snow coverage and the development of a highly continental air mass in the mid and high latitudes of Eurasia (Farrera et al., 1999; Harrison et al., 1996).

Most of the Tibetan Plateau and western China remained relatively wetter than today, and the Middle East was characterized by high lake levels (Figure 5(b)). There appears to have been a wet belt from the eastern Mediterranean, through Central Asia to western China. The high lake levels were interrupted at $100\text{--}105^{\circ}$ E, that is, Qinghai Lake (100.5° E) and Baijian Paleolake (104.2° E; Pachur et al., 1995). This pattern suggests that they may have resulted from a southward shift and strengthening of the Westerlies under the influence of the high-latitude

Figure 4 (Continued)

ice sheet and very low evaporation over an extremely cold plateau surface (Farrera et al., 1999; Qin and Yu, 1998).

Late MIS-3

The records of the period are mainly concentrated in the Tibetan Plateau, Yunnan Plateau, and western China, and they are generally characterized by wetter conditions than today (Figure 5(c)). Individual lake studies on the Tibetan Plateau have provided several high lake-level records during the interval 35–30 ka BP, such as Bangong Co (79 m higher than today), Selin Co (30 m higher), Tianshuihai Lake (40–60 m higher), Qarhan Salt Lake (29 m higher), Gaxun-Sogo Co (22–30 m higher), Nam Co (18–26 m higher) and Baijian

Paleolake (30 m higher) (Hu, 2001; Li, 2000; Pachur et al., 1995; Zheng et al., 1989; Zhu et al., 2003). In contrast, two sites from the Arabian Plateau and Taiwan registered a more negative P-E balance than today.

The large extent of wet conditions in Asia suggests a major increase in annual precipitation, possibly resulting from an enhanced southwest monsoon. This circulation change may have coincided not only with a large land–sea temperature difference between the equatorial Indian Ocean and the Tibetan Plateau, but also a strong Australian high-pressure system, which strengthened the south Asia monsoon via the trans-equatorial air mass: an air flow in the southern hemisphere that passes across the Equator towards the Asian subtropical areas of the northern hemisphere in the summer season (Shi et al., 2001).

Figure 4 (Continued)

Lake-Level Change and Paleoclimate Modeling

On a late-Quaternary timescale Asian lake-level changes are clearly linked with climate change. The observed data can indicate the magnitude, direction, and timing of climate changes. However, it has proved harder to develop an

understanding of the mechanisms underlying the climate changes. The advent of paleoclimate simulations using physically based numerical models (e.g., Jousaume et al., 1999; Kutzbach et al., 1998) represents a major advance in our understanding of the underlying climate mechanisms. General circulation models (GCM) and regional climate models can

Figure 5 (a)–(c) Spatial patterns of lake-level changes in Asia at: (a) 6 ka BP; (b) 21 ka BP; and (c) 35 ka BP (sources: OLLDB, FUSDB, and CLSDB). Large and small crosses represent much wetter and wetter than today, and large and small triangles represent much drier and drier than today. Circles represent similar to today.

simulate atmospheric precipitation and effective moisture, and simulations can be compared with the character and spatial distribution of past lake-level changes.

A paleoclimate simulation reflects the status of key physical parameters that drive climate change. Many climate simulations for 6 and 21 ka BP use the Paleoclimate Modeling and Intercomparison Project (Joussaume et al., 1999) values for insolation, ice cover, sea-surface temperatures, and atmospheric CO₂ concentrations. Simulations for 35 ka BP (Yu et al., 2007) reflect a positive insolation anomaly and reduced extent of the Laurentide and Fennoscandian ice sheets (50–70% of those during the LGM). Furthermore, Asian vegetation cover

reconstructed from paleoecological records has been used in paleoclimate simulations in order to examine land-surface effects on climate (e.g., Yu et al., 2001b). The results of paleoclimate simulations for the key periods of 6, 21 and 35 ka BP and their implications for our understanding of the mechanisms of Asian lake-level changes are introduced below.

The Climate at 6 ka BP

Paleoclimate simulations for 6 ka BP produce significantly warmer summers in the low and mid-latitudes of Asia (Joussaume et al., 1999; Qin et al., 1998; Yu et al., 2001b); vegetation feedback reversed orbitally-forced winter cooling and resulted in a warmer winter (and higher mean annual temperature) than present (Figure 6(a)). Simulated increases of precipitation in Arabian, Indian, and Tibetan plateaus were induced by a significantly enhanced Asian monsoon. The reduction in precipitation over southern China (Figure 6(b)) is linked with adjustments in the position and strength of the Pacific Subtropical High induced by orbital forcing.

A climate simulation for 6 ka BP using the regional climate model RegCM2 has generated a high-resolution (120 × 120 km² per gridpoint) climatic image at the scale of Asia (Zheng et al., 2004). The increase in Northern Hemisphere summer insolation at 6 ka BP led to a significant temperature increase in the mid- and high latitudes in Asia and enlargement of the sea–land thermal contrast, which in turn caused the strengthening of Asian summer monsoon and hence the west- and northward expansion of its rain belt. The 6-ka BP P-E simulation (Figure 6(c)) shows a prominent increase over most of Asia, and the low- and mid-latitude precipitation belts extended westward and northward. The 850-hPa summer southerly wind components show that along with the strengthening of the Asian summer monsoon, the north border of southerly winds advanced markedly northward and westward, which favors intrusion of warm and wet flow from the South China Sea and West Pacific into the interior of Asia. The 850-hPa winter northerly wind is weakened, and the advection cooling into East Asia correspondingly reduced. Consequently, there are annual convergences over Mongolia, north-northeast China, Tibet, and India, indicating more moisture and frequently wet conditions. Conversely, divergences over southern China contribute to dry conditions (Figure 6(d)).

The Climate at 21 ka BP

GCM simulations (e.g., COHMAP Members, 1988; Kutzbach et al., 1998; Yu et al., 2003) show global annual temperatures, including those for Asia, generally lower than today. Across most latitudes globally, P-E values were also lower (with the exception of North America south of the ice sheet and the Mediterranean, where southerly displacement of the Westerlies enhanced precipitation). Simulations of less precipitation over most areas of Asia (Figure 7(b)) and negative P-E anomalies in the Southeast Asian tropical area and East Asian lowlands are linked to a weakened Asian summer monsoon and a persistent winter Mongolian High. The simulated increases in annual precipitation and P-E in west China were due to a southward and eastward shift in the position of the Westerlies plus a decrease in evaporation in the cool conditions that prevailed

across Asia (temperatures simulated at 4–16 °C lower than today: [Figure 7\(a\)](#)). A regional climate model simulation of the annual P-E pattern for the LGM ([Figure 7\(c\)](#)) reveals two patterns of moisture flux increase over the Tibetan Plateau in the annually averaged 850 hPa map: one from the East China

Sea and the other from the northern Bay of Bengal ([Zheng et al., 2004](#)). These patterns are consistent with the observed lake-level changes ([Figure 7\(d\)](#); the east-Asian region and adjacent seas were areas of net moisture output and substantially reduced precipitation).

Figure 6 (a)–(c): GCM-derived paleoclimate simulations for 6 ka-BP shown as anomaly maps (departures from present values). (a) mean annual temperature (°C); (b) precipitation (mm d⁻¹); (c) P-E (mm d⁻¹). Values derived from [Yu et al. \(2001b\)](#) and the regional climate model simulations of [Zheng et al. \(2004\)](#). Figure 6(d) shows moisture conditions indicated by the lake-level records for comparison (symbols the same as [Figure 5](#)).

Figure 7 (a)–(d) As in [Figure 6](#), but for 21 ka BP.

The Climate at 35 ka BP

Regarding the period 30–35 year BP (late MIS3), a GCM simulation of the Asian climate focused on 35-ka BP, the period of lake high-stands in Tibet and northwest China, shows higher temperatures compared with present in most areas of low- and mid-latitude Asia (**Figure 8(a)**), reflecting forcing by increased insolation (Yu et al., 2007). Lower temperatures than present at high latitudes mainly reflect the cooling effects of the Quaternary ice sheets. The simulated monsoonal precipitation belt is shifted northwards (**Figure 8(b)**); the annual P-E simulation shows conditions wetter than today in the Indian Peninsula, Tibetan Plateau and northern China, but drier in southern China (**Figure 8(c)**). Changes in surface heating patterns (i.e., larger differences in insolation between high and low latitudes) and circulation (an increase in meridional exchange but a decrease in east–west exchange) and land-surface conditions (extension of southern forests in East Asia) led to wet conditions in inland areas that are dry today.

The atmospheric circulation changes over Asia reveal the likely mechanisms behind lake-level change at 35 ka BP (**Figure 8(d)**). Strong precession over low latitudes compared with modern orbital conditions and Quaternary ice sheets at high latitudes were important factors affecting the Asian 35 ka BP climate: the temperature decreased at mid-high latitudes but increased at low latitudes, which generated larger south–north temperature gradients compared with today. In turn, moisture transport from low to high latitudes was enhanced, and monsoonal precipitation belts were shifted northwards to Northwest China, while dry conditions developed in South China. This climatic pattern at 35 ka BP is linked to the occurrence of larger lake areas and higher lake levels than today in Tibet and Northwest China (Li, 2000; Pachur et al., 1995; Shi et al., 2001; Zheng et al., 1989; Zhu et al., 2003).

Recent Progress and Future Outlook

Asian lake-level studies have provided a scientific context for understanding environmental changes in the future, both as regional histories of hydrology and climate in terms of processes, frequency, and trends, or as benchmarks for paleoclimate model evaluation and testing. The accuracy of model-based predictions of future climate cannot be directly assessed, but the models used to generate such predictions can be tested by simulating the climates of times in the past and comparing these simulations with paleoclimate reconstructions. This is one of the important goals of lake-level studies. However, there remain considerable uncertainties about the past lake-level changes, which will in turn affect model evaluations and projections for the future.

During the last ten years, additional lake-level studies from Asia have been carried out using multiple proxies from lacustrine sediments (**Table 1; Figure 9**). There has been progress toward the filling of key geographical gaps in data, in applying tools to derive quantitative estimates of lake-level change, in the use of high-resolution sampling to achieve time series resolved at 10^1 – 10^2 years, and in deep-lake drilling to obtain million-year records. For example, at Qinghai Lake (No. 15 in **Figure 9**) on the Tibetan Plateau sediment cores have been taken to reconstruct a long lake history, with high-resolution sampling and many dates on core material. The 795-cm long core was sampled at 1–4 cm intervals (22–90 years resolution; Shen et al., 2005a,b). Such high-resolution studies have revealed short-term climatic oscillations, for examples, low lake levels coincided with the Younger Dryas stadial, and sharp drying lasting ca. 100 years was centered on the 8.2 ka BP the cooling event, with other lake level fluctuations occurring between 8.5–7.8 ka BP.

Figure 8 (a)–(d) As in **Figure 6**, but for 35 ka BP.

OSL, TL, ESR, Us, Tep, and Mag represent dating by optical stimulated luminescence, thermoluminescence, electron spin resonance, uranium-series, tephrochronology, and magnetostratigraphic chronology, respectively.

Lake level changes have recently been reconstructed via quantitative approaches. For example, at Nam Co (No. 8 in [Figure 9](#)) on the Tibetan Plateau, which has a lake area of 1920 km², past water depth was inferred from an ostracode-based transfer function derived from 25 surface sediment samples taken between 47 and 93.5 m depth ([Zhu et al., 2010](#)). The percentages of four dominant species were used to infer paleo water-depth values, of which the maximum inferred water depth was about 63 m and the minimum 15.7 m. Water depth during the last 8400 years has been reconstructed from a 332-cm long sediment core. Several stages are apparent: in the early mid-Holocene water depth was much lower than today, dropping from an estimated 50 m to 20–30 m between 8400 and 6800 years BP. The lake water depth remained at this low stand between 6800 and 5700 years BP but then gradually deepened to around 50 m during 5700 and 2900 year BP. A cold-dry event occurred between 1700 and 1500 years BP, when lake depth decreased slightly, but the lake then continuously deepened to 60 m after 1500 years BP. The study shows that ostracode assemblages are not only indicative of

cold-warm conditions, but may also be used to imply the dry-wet status of a lake by inferring water-depth variations.

Many Asian countries are currently facing severe problems in connection with lacustrine environments and water resources, and these are expected to increase in the twenty-first century: diminishing lake areas, salinization, and eutrophication. To meet these challenges, lake-level studies should pay more attention to the historical period in order to understand both natural evolution and anthropologic impacts. Some studies have attempted to apply lake-level records to scenarios of regional hydrological changes in lake basins. Because catchment water balance and lake water levels in arid and semiarid areas of China are sensitive to direct and indirect changes related to precipitation and temperature, lake-level records not only show lake responses to climate changes in the past, but they can be used as analogs to estimate lake changes with future climate change. Four large lakes: Aibi Lake (542 km²), Qinghai Lake (4635 km²), Daihai Lake (134 km²), and Hulun Lake (2339 km²) which lie on a west-to-east transect across northern China (locations see No. 1, 15, 23 and 32 in [Figure 9](#)), have

Figure 9 Lake locations and the record lengths updated for lake level studies since 2000 (lake numbers and references same as Table 1) from the CLSDB (Yu et al., 2001a). Star sites are deep-lake drilling cores in Asia. Data sources listed in Table 1.

been used for such studies (Yu and Shen, 2009). Lake-level time series derived from the gaged period of the past 50 years and from reconstructions of the past 30 ka BP provide frequencies and amplitudes of variation at different time scales; these are used in simulating the probability of future water-level changes. GCM climate simulations based on Intergovernmental Panel on Climate Change (IPCC) scenarios were applied to the four lake basins. Given a ~95% chance of a temperature increase in the coming 50 years, the predicted twenty-first century variation in water level is about $\pm 50\%$ in Qinghai Lake, $+25$ to $+70\%$ in Daihai Lake, $+30\%$ to -20% in Hulun Lake and $\pm 20\%$ in Aibi Lake (Yu et al. 2009). The scenarios can be used to evaluate the probability of changes in lake volume occurring over the next 50 years, and they will provide an important basis upon which to assess uncertainties in future hydrological changes.

Introduction

Australian lakes span a wide range of physiographic and climatic regions and are generally characterized by shallow depths, saline water, and discontinuous records. Coastal lagoons with continuous, spasmodic, or groundwater connections to the ocean are common but will not be considered in this article. Small fresh-water perennial lakes occur in a very limited area of the mainland around Mt. Kosciuszko, which was glaciated during Pleistocene cold phases, and are larger and more abundant in the more widespread glaciated regions of Tasmania. Most lake-level studies have focused on a variety of basins of the semiarid and arid interior, crater lakes in Quaternary volcanic regions, particularly in Western Victoria and also in northeastern Queensland, and some long-lived structural basins formed by drainage disruption due to tectonic uplift of the Eastern Highlands.

Australia is dominated by arid and semiarid environments in the interior. Higher rainfall zones are restricted to the southern, eastern, and northern margins and are seasonal with northern rainfall highly seasonal. Precipitation is derived in the north from the summer monsoon and in the south from winter-westerly frontal systems. A broad zone of weak or mixed seasonal dominance covers much of arid and semiarid Australia and extends from the northwest to the southeast (Figure 1). Precipitation can also be derived from the east. High-magnitude events recorded east of the Eastern Highlands divide are associated with stationary offshore cyclonic systems that are derived from either tropical or winter-westerly circulation. In the modern system, significant rainfall from these events rarely occurs west of the divide and does not influence arid-zone hydrology. Aridity in Australia is not due to an absolute lack of water vapor in the air masses, but rather due to a lack of a mechanism for triggering of precipitation by rising air masses due to either convective or orographic processes. Therefore, climate change that results either in changes in latitudinal position of monsoon or winter-westerly-derived precipitation or in enhanced convection can significantly affect lake levels.

Bowler (1981, 1986) examined the spatial variability and hydrologic evolution of Australian lakes and classified them according to catchment area/lake area ratios. These are related to functions of climate and runoff, and they elegantly illustrate the factors controlling the paleoclimatic sensitivity of lakes. Lakes close to the equilibrium line in this relationship have water budgets almost in balance and tend to be ephemeral, or nearly so. These lakes are the most sensitive to climate change: even small changes of climate can have a dramatic impact on sedimentary processes and hence the preserved sediment records. On the other hand, lakes at the wet end of the spectrum (lakes with extremely large catchments and those occurring in high rainfall zones or both) have strongly positive water budgets and will only respond to extremes of climate change, if at

all. Bowler's classification recognized a hydrologic continuum from wet to dry that operates both spatially, as climate varies across the continent, and through time, as climate has varied during Quaternary glacial–interglacial cycles. Under full fresh-water conditions, wind-induced wave erosion and sediment transport produce smooth shorelines and quartz-rich beaches and foredunes on the downwind margins; sediments are terrigenous and rich in biological carbonates. With negative hydrological budgets, groundwater and salinity dominate. Salts (particularly gypsum, halite, and sodium sulfates) crystallize displacively in the lake sediments, disrupting them and allowing deflation of sand-sized sediment aggregates and salts by the dominant wind. Clay-rich dunes or lunettes form on the downwind shoreline, and finer dust material is spread further down basin (Bowler, 1973, 1983; Magee, 1991). At the extreme dry end of the spectrum, surface-water cover is extremely rare and groundwater processes dominate, producing systems with highly irregular outlines and multiple islands. These groundwater playas are also insensitive to climate change because, lacking the necessary amplification of a large catchment area, evaporation always exceeds inflow. Thus, they will not change their state even in response to a considerable wetting of the climate.

The features described above mean that Australian lakes do not have long, continuous high-resolution records, but they are nevertheless very often highly sensitive to climate change. Extraction of paleoclimatic records rarely requires use of complex proxies dependent on sophisticated, expensive, and time-consuming analyses. Sequences from many Australian lakes have so much variation in their sedimentary record that a simple log of deep- or shallow-water clastics, evaporites, macrofossils, color, soils, deflation events, etc., can provide a rich paleoclimatic record. Wide variations in sedimentology and biota also undoubtedly extend the opportunities for applying different dating techniques and obtaining a reliable chronology.

Eastern Highland Tectonic Basins

Lake George is a closed basin in a fault angle depression astride the Eastern Highlands divide. It lies at 35° S at an elevation of 670 m about 100 km from the coast (Figure 1). The modern lake has an excellent historic record back to 1820 of variations from dry to 7.3 m water depth, which correlates with climate variability. Shoreline evidence has been studied by Galloway (1965) and Coventry (1976) and central basin sediments and pollen by Singh et al. (1981). Paleomagnetic reversal dating has established a firm chronology for the basin fill back to about 3 My and an extrapolated age for the origin of sedimentation as middle Miocene or older (Singh et al., 1981). Lacustrine deposition has not been continuous, though drier episodes are marked by pedogenesis rather than the deflation

of lake sediment that characterizes arid-zone basins. Deep-water lacustrine conditions extend from the base of the cored sequence at 72 m (between 4.1 and 7 Ma) to a major discontinuity at 51.5 m, where evidence of deep weathering and slope mantle deposition indicate a long hiatus in lake deposition. Lacustrine conditions returned to the basin resulting in increased depositional rates above 21.5 m (0.94 Ma) and dominated the Brunhes magnetic chron (last 790 ka) with regular cycles over the past 400 ka. The late Quaternary shoreline evidence indicates overflow (~36 m water depth) between 27 and 21 ka BP and subsequent, lower highstands (between overflow and modern levels) at 15, 8, 5, and 3 ka BP. However, this radiocarbon chronology is based on early conventional dates and, with an abundance of nearshore and beach sandy sediments available, it should be revised by a combination of optically stimulated luminescence (OSL) and accelerator mass spectrometry ^{14}C dates that target reliable microfossils with rigorous pretreatment.

Western Victorian Volcanic Lakes

The newer volcanic region of Western Victoria has widespread Quaternary eruptive centers and numerous lakes that formed predominantly as crater lakes and maars. These lakes vary in age, depth, and salinity, and are mostly closed basins with respect to surface-water hydrology in the modern setting. Water depth and salinity have varied through time in response to Quaternary climate changes, and lake levels and past climates have been deduced from (1) shoreline and lacustrine sediments and (2) paleosalinity estimates based on various biological and chemical proxies. Many basins have been studied, and the

best lake-level records come from Lakes Bullenmerri, Gnotuk, and Keilambete, particularly the last (Figure 1). Here, close agreement exists between shoreline and sedimentary facies (Bowler, 1981), pollen analysis (Dodson, 1974), ostracod species abundance (De Deckker, 1982), and ostracod shell trace element and isotope geochemistry (Chivas et al., 1993). Keilambete (Figure 2) was dry prior to about 10 ka BP with a soil developed on ancient lacustrine sediments. Filling began about 10 ka BP, and more sustained rising levels after 8.5 ka BP resulted in overflow (at slightly <40 m water depth) from about 7.5 to 5.5 ka BP. Lake levels then declined and reached a minimum between 3.2 and 3.6 ka BP, subsequently oscillating at generally low levels until rising again at about 2 ka BP. A relatively constant water depth was maintained at about 25 m until a sustained drop recorded historically since about AD 1850. The modern lake lies at depths as low as anything seen since filling began at 10 ka BP.

Bowler (1981) recognized that the Western Victorian crater lakes were climatically very sensitive, and with their simplified hydrology they had the potential to be virtual rain-gauge records – if the P/E relationship could be unraveled. Jones et al. (2001) constructed a water-balance model for Lakes Bullenmerri, Gnotuk, and Keilambete, calibrated by detailed historical lake-level records and historical climate records (rendered reliable by extensive investigative reduction of dubious data). This water-balance model allowed a detailed record of P/E for the record of the three lakes (Figure 2), since 16 ka BP for Bullenmerri, and since 10 ka BP for Keilambete and Gnotuk (Jones et al., 1998).

Coring techniques used in the crater lakes, suitable for the soft sediments deposited in the postglacial high-water events, have not been able to penetrate the compacted/cemented soil

Figure 2 Lake-level records from Lakes Keilambete, Bullenmerri, and Gnotuk, volcanic crater lakes in western Victoria. Modified from Jones RN, Bowler JM, and McMahon TA (1998) A high-resolution Holocene record of P/E ratio from closed lakes, western Victoria, Australia. *Journal of Hydrology* 246: 159–180.

horizons formed during the Last Glacial Maximum (LGM) dry period. Many of the craters extend back through a number of glacial cycles and have the potential for high-quality long, though discontinuous, lake-level records. Many of the older craters are filled with sediment and maintain swamp rather than lacustrine environments. Cores from these craters, some with long records, have been analyzed for pollen but not studied specifically for lake levels (D'Costa and Kershaw, 1997). Similarly, a number of crater lakes and sediment-filled swamp craters in north eastern Queensland have been cored but only analyzed for pollen sequences (e.g., Kershaw, 1986; Turney et al., 2001).

Arid-Zone Lakes

Australia's arid desert region is a broad zone of moderately low, highly variable rainfall with mixed seasonal dominance, with the semiarid margins extending into the monsoonal summer-rainfall zone to the north and the westerly winter-rainfall zone to the south. Flood-out, overflow or terminal lakes, dominated by surface-water hydrology, are associated with coordinated

drainage of the very large Murray–Darling and Lake Eyre Basins of the southeast and northeast, respectively, with large systems such as Lake Woods (NT) and Lake Gregory (WA), and with smaller systems such as Lakes Buchanan and Gallilee (Qld; Figure 1).

Murray–Darling Basin

Coordinated external drainage in the arid zone is restricted to the Murray–Darling Basin, where moisture sources extend from winter westerlies for the southern Murray tributaries in Victoria to summer tropical systems for the upper Darling tributaries in Queensland. Some of the tributaries in this basin can be influenced by easterly derived moisture, and many rise in the highlands of Victoria and southern and northern NSW, which are subject to complexities of snow pack and periglacial conditions, much expanded in the past (Barrows et al., 2004). Much of the Murray–Darling system is characterized by very low-gradient fluvial plains with abundant ephemeral lakes, of variable size and origin. Hydrologically, most of these are flood-out lakes; they lie adjacent to fluvial systems with connecting channels and are filled by passing floods then partially emptied as the flood peak passes and flow reverses in the feeder channel. Evaporation then lowers lake level until the next flood replenishes the lake, and deflation of the bed during dry periods prevents filling by sediment. Flood-out lakes can thus contain long but discontinuous lake-level records that reflect the flood history of the adjacent fluvial system. In contrast to the flood-out lakes, the Willandra Lakes are an overflow system of now-dry lakes fed by a distributary of the Lachlan River, the Willandra Billabong Creek, which rises in the Eastern Highlands north of Canberra. In common with most Murray–Darling Basin lakes the Willandra Lakes are characterized by lunettes, lee-side eolian accumulations derived from the lake basins. These are high-quality archives of the hydrologic state of the lake, with quartz foredune sediments representing lake-full conditions, gypseous, clay pellet-rich sediments reflecting saline groundwater domination, and soils forming when deposition is not occurring. When full, the lakes of the system provided rich resources for human occupation, and archaeological evidence is abundant in the lunette depositional sites adjacent to the lakes.

Relatively recent severe erosion of some of the Willandra Lakes lunettes has exposed their internal stratigraphy, and long-term sedimentary and chronological studies (summarized in Bowler (1998) and Bowler et al. (2003)) have elucidated a complex history of wetting and drying cycles between 60 and 15 ka (Figure 3) and provided an environmental and chronological context for the associated archaeology. Older phases of lake activity are preserved as mostly buried sedimentary units on lake floors and as lunettes capped by well-developed soils. These ancient wet phases are generally poorly dated. Some luminescence dates from the youngest of them, the Goolgol lunette unit, indicate an age in the range 100–130 ka. By 60 ka, at the latest, the lakes had refilled and the system was full, fresh, and overflowing; quartz-rich beach and foredune lunette sediments of the Lower Mungo unit were deposited throughout the system at this time. At about 42 ka, a significant drying episode began, marked by a transition to Upper Mungo

Figure 3 Lake-level record from the Willandra Lakes, Murray Basin, southwestern New South Wales. Modified from Bowler JM (1998) Willandra Lakes revisited: Environmental framework for human occupation. *Archaeology in Oceania* 33: 120–155; Bowler JM, Johnston H, Olley JM, et al. (2003) New ages for human occupation and climatic change at Lake Mungo, Australia. *Nature* 421: 837–840.

unit sediments, which are rich in clay pellets derived via deflation that is controlled by saline groundwater. The Mungo unit is followed by the Arumpo and Zanci units, which also record wetter, surface-water-dominated conditions followed by lake-floor deflation under drier conditions. The trend is toward increasingly effective dry phases and culminates in a thick sequence of gypseous pelletal clay deposited during the Zanci unit saline groundwater-deflation stage (22–19 ka). Following this intense dry phase at the glacial maximum, there is a brief return to wetter conditions that brought water to the northern lakes of the system (Mulurulu and Garpung) and deposited the Mulurulu unit at about 18 ka. Since then the lakes have remained dry, with regionally low water tables, and soils have formed over the landscape. Page et al. (1996) report a thermoluminescence (TL) chronology for a stratigraphic sequence of fluvial units associated with paleochannels of the Murrumbidgee River on the Riverine Plain, south of the Lachlan system. There is general accord with the Willandra Lakes sequence in the chronology of the Yanco, Gum Creek, and Kerarbury units in the 50–15 ka range, but an earlier phase, the Coleambally Unit, dated to late marine isotope stage (MIS) 5 (80–105 ka) has no known equivalent units in the Willandra Lakes.

Lake Eyre Basin

Until luminescence dating became available, little was known about the Quaternary paleohydrology of fluvial and lacustrine systems that are northern monsoon-fed with coordinated internal drainage. The lacustrine records from Lakes Eyre, Woods, and Gregory, and the fluvial records from the Lake Eyre catchment are now dated back to 2–300 ka, with the last 130 ka relatively well constrained. All these records indicate wetter conditions associated with the warm interglacial phases and drier conditions associated with the cold glacial phases.

Lake Eyre has a complex suite of deep-water, nearshore, beach, lunette, and inflowing stream sediments that provide the most complete and best dated monsoon-derived lake-level record over the past 150 ka (Figure 4; Magee and Miller, 1998; Magee et al., 1995, 2004). Prior to 130 ka, in MIS 6, the lake was dry, and deflation had lowered the basin floor to levels lower than today's playa floor and lower than that of the LGM. Early in MIS 5, at around 130 ka, there was an abrupt change to lacustrine conditions and establishment of a salinity-stratified perennial water body, 25 m deep with a shoreline at about 10 m Australian height datum (AHD). The lake was fed by enhanced flow from the Diamantina and Cooper systems.

Figure 4 Lake-level record from Lake Eyre, northern South Australia. Modified from Magee JW, Miller GH, Spooner NA, and Questiaux D (2004) Continuous 150 k.y. monsoon record from Lake Eyre, Australia: Insolation-forcing implications and unexpected Holocene failure. *Geology* 32(10): 885–888.

This included overflow from a combined Frome–Callabonna–Blanche–Gregory megalake at 18 m AHD, fed via the Strzelecki Creek, a distributary from the Cooper (DeVogel et al., 2004). While the hydrological response to climate change in such an extremely large and complex catchment is unlikely to be linear, the conditions of early MIS 5 must indicate an enhanced Australian monsoon. After a brief drying, lower-level perennial lacustrine conditions returned later in MIS 5, and there was considerable variation in water level and salinity. Drying and deflation of the basin occurred again, followed at about 65 ka by the last, relatively short, high-level lacustrine conditions, which constructed a beach at –3 m AHD. Between 60 and 50 ka, the lowering of water table associated with the transition from the previous high-lake events of stage 5 resulted in a major deflation event that effectively excavated the modern Lake Eyre playa basin. A low-level (–10 m AHD), poorly dated lacustrine event occurred in stage 3 and was followed by prolonged dry conditions with episodic deflation from about 35 to 14 ka. At about 12 ka low-level, semiperennial lacustrine conditions (below –10 m AHD) returned to the basin, indicating renewed enhancement of the monsoon, but less effectively than in the previous interglacial (early MIS 5). The modern ephemerally flooded playa conditions were established at about 3–4 ka, indicating a change to a drier monsoon regime marked by more extreme events.

Older deposits sedimentologically and stratigraphically similar to those of the last glacial cycle occur east and northeast of the current playa and have luminescence dates indicating that similar monsoon enhancement occurred in MIS 7 and probably earlier interglacials. However, the migration of the depocenter through time and the destruction of pre-MIS 5 shorelines and beach ridges preclude the possibility of comparing the lake area through time and consequently of assessing long-term trends in monsoon strength.

The fluvial sequences of the middle and upper reaches of the Lake Eyre Basin have been extensively studied and dated by luminescence, mostly TL by Nanson et al. (1991, 1992). They have a record in accord with that from Lake Eyre, showing enhanced activity in interglacials. Nanson et al. (1992) report the greatest number of MIS 5 dates centered on about 109 ± 4 ka. They interpret this as indicating that the peak of fluvial activity occurred somewhat later in the previous interglacial than indicated at Lake Eyre. An alternative explanation

is that the fluvial dates are biased toward the end of a phase of activity, as the river continually reworks sediments within the valley tract. In good agreement with the Lake Eyre record, from an upstream Diamantina tributary the Western River, Nanson et al. (1992) reports a minor enhanced regime in stage 3, and a Holocene enhancement much less significant than the last interglacial. The longer record from the rivers provides strong indications of a trend of decreasing monsoon strength through successive interglacials. Maroulis (2000) reports that the middle Cooper had reworked virtually the whole of its valley tract in MIS 7, less than half in MIS 5, and very little in the Holocene, when suspended-load streams contrasted strongly with the sand-transporting systems of earlier interglacials. Flood-out lakes are commonly associated with many of the Lake Eyre Basin rivers, including the very large Lake Yamma Yamma in southwest Queensland. These are sparsely studied but should contain lake-level records reflecting the stream flood histories.

Other Monsoon-Fed Terminal Lakes

Lake Woods and Lake Gregory are both moderately large modern lakes in Northern Australia, which vary in accord with the strength of monsoon events, particularly cyclonic activity in their catchment streams, Newcastle Waters and Sturt Creek, respectively. Both modern lakes lie within the basin of much larger megalakes. Large sand-dominated lunette beach ridges occur on the downwind western margins, and longitudinal dunes are developed on the megalake floors inside the outer shorelines. The Lake Woods outer shoreline is a single ridge with complex internal stratigraphy for most of its length, but it splits to multiple crests at its northern extremity. Bowler et al. (1998) report luminescence dates indicating a high-level lacustrine event early in MIS 5, a lower-level inset event in MIS 3, and a much lower lake, similar to the modern water body, in the Holocene. They also indicate that an earlier high-level MIS 7 lacustrine phase occurred, but the stratigraphic and chronologic definition is not sufficient to identify a longer-term trend in lake area and monsoon strength. At Lake Gregory, a series of shoreline ridges between the large outer shoreline and the modern water bodies suggests a successive contraction of the size of the megalake through time. Bowler et al. (2001) report TL dates from shoreline ridges and longitudinal dunes on the megalake floor, which indicate an age of about 300 ka for the outer shoreline, 200 ka (MIS 7) for an intermediate shoreline, and MIS 5 ages for the shoreline just outside the modern water bodies. This suggests a clear long-term waning trend in megalake size and consequently in monsoon strength. However, the relatively poor quality of the TL chronology, as indicated by the extremely low precision of the dates, suggests caution in interpreting these results. Recent redating by OSL (Miller and Magee, unpublished data) of the same shoreline ridge site dated to 200 ka by TL, indicates a much younger age.

Groundwater Lake/Playa Systems

Much of the arid zone, particularly in central and western parts of the continent, is characterized by uncoordinated drainage

and numerous large and small playa lakes, which are mostly groundwater-fed systems often occupying now-defunct former valleys and drainage lines of Tertiary or earlier age. Many of these systems lack effective catchments and never act as surface-water lakes even in wetter climate phases. These systems, termed boinkas by Macumber (1991), generally do not provide lake-level records, but where wetter phases result in enhanced groundwater inflow, deposits that are indicative of wetter conditions may occur, such as the gypsum-rich shoreline marginal dunes of Lake Amadeus (Chen et al., 1991). Some of the groundwater-dominated playas have presently defunct catchment drainage and may have sedimentary sequences and shorelines indicating former surface-water phases; these have the potential to provide lake-level records.

Few of the groundwater playa system records have been analyzed. In Central Australia, the large groundwater-dominated playas Amadeus and Lewis both lie within the zone of mixed rainfall seasonal dominance, but their hydrologies probably chiefly reflect a monsoon signal, particularly that of Lake Lewis, which lies north of the McDonnell Ranges. Both playa sequences have basal clay-rich units indicating much wetter lacustrine conditions; these are constrained to the lower Quaternary by paleomagnetic dating (Chen et al., 1993; English et al., 2001). A later transition to playa environments is indicated by evaporites and deflation events in both basins, but the chronology of these events is poor at Amadeus due to lack of luminescence dating and at Lake Lewis because of high-dose rates that lead to saturated dates.

Paleoclimatic Summary

Bowler et al. (1998) examined the paleoclimatic implications of the enlarged Lake Woods using the P/E and runoff efficiency relationship established earlier (Bowler, 1981, 1986), and they concluded that enhanced monsoon precipitation was required to explain the lake enlargement. Chappell (1991) also considered the hydroclimatology of the megalakes and concluded that the enlarged lakes could not be explained by reduced evaporation due to temperature reduction. Rather, enhanced precipitation or runoff efficiency or a combination of both was required. He pointed to empirical evidence of catchment runoff and rainfall gauging from the modern northern Australian Daly River system, which demonstrates significant increase in runoff efficiency as precipitation increases. Chappell's (1991) review of paleoclimate records in eastern and central Australia was prepared just before the luminescence chronologies became available. At that time, the available evidence pointed to the central and northern Australian megalakes being coincident with early stage 3 lacustrine events in the Murray Basin. Chappell pointed out the conundrum of megalake phases requiring enhanced precipitation/runoff at a time when sea level and temperatures were lower, and when pollen records from Lynch's Crater in the northeast (Kershaw, 1986) suggested somewhat lower precipitation than in the Holocene, when there were no megalakes. Subsequent luminescent dating of the megalakes to the last interglaciation has essentially resolved this issue.

Monsoon-fed systems clearly indicate a strong enhancement of the monsoon during warm interglacial periods, a

weaker enhancement in interstadials, and inactivity during cold glacial phases. There is evidence from the rivers of the Lake Eyre Basin of a long-term waning trend in monsoon strength through successive interglaciations, but evidence for this trend is equivocal or lacking at other sites. All records indicate that during the Holocene monsoon enhancement is much less effective than during the previous interglaciation. It is not clear if this relative failure of the Holocene monsoon is anomalous or part of a long-term trend.

On the southern desert margin, the best winter-westerly records come from the lakes and rivers of the Murray Basin. The winter-westerly fed fluvial systems show an MIS 5 enhancement that appears to be later than that of the MIS 5 monsoon systems. Both lacustrine and fluvial winter-westerly fed systems show strong enhancement in MIS 3. The Murray Basin sequences are the best available records for winter-westerly influenced arid-zone hydrology, but they undoubtedly are subject to other influences. The catchments of the Lachlan, and to a lesser extent the Murrumbidgee, can both be influenced by summer rainfall and perhaps by an easterly derived component. Both catchments, especially the Murrumbidgee, are at relatively high altitude and are likely to have experienced periglacial and snow pack conditions during cold glacial stages, which must have enhanced seasonality of flow regimes. It is difficult to interpret a clear precipitation signal from these systems, especially the streams closer to the highland sources. This complexity of catchment processes is a probable explanation for the apparently anomalous high LGM lake level at Lake Urana (Page et al., 1994; Figure 1) when compared to the Willandra record. Ideally, future investigation of winter-westerly precipitation should target lakes at the desert margins of Eyre Peninsula or the South West of Western Australia, where no other precipitation sources exist and other catchment complexities are minimized. Preliminary results from the Scrubby Peak Lake, northern Eyre Peninsula (Magee et al., unpublished data) indicate an MIS 5 wet phase (100–110 ka) and LGM deflation, but no MIS 3 wet phase, which is difficult to reconcile with the Murray Basin records.

Widespread aridity, dune activation, and low or dry lakes are associated with the LGM. Evidence from Northern Australia (Wyrwoll and Miller, 2001) suggests reactivation of the monsoon by 14 ka, and by 10–12 ka, lakes across the continent were rising. Central and northern Australian lakes existed at relatively low levels before falling to modern dry or ephemeral levels from about 3 ka. The highly sensitive Western Victorian volcanic lakes demonstrate a more complex Holocene record with a significant maximum, when many overflowed, centered on about 6 ka, and lower levels from about 3 ka. Since just prior to the arrival of Europeans, there has been a significant lowering related to a shift in the climate regime.

In summary, there are indications that the two climatic systems that influence Australian precipitation, the monsoon and the winter westerlies, have both been enhanced and contracted during different parts of the glacial–interglacial cycles and that these changes may have been out of phase, with westerly enhancement occurring later than the monsoon in MIS 5 and being much stronger than the monsoon in MIS 3. Holocene monsoon enhancement is much less than during the previous interglaciation, and it is not yet certain if this is anomalous or part of a longer-term trend. If anomalous,

it implies a change in boundary conditions, and a possible explanation is that the arrival of humans (50 ± 5 ka) and consequent changed fire regime, caused sufficient ecological change in monsoon catchments to cross a threshold in the hydrological response (Magee et al., 2004; Miller et al., 2005). To investigate these questions advances in a number of areas are required: stratigraphic control of lacustrine and fluvial sequences, accuracy and precision of chronologies, hydrologic modeling of large complex nonlinear catchments, recognition of catchment response thresholds, our understanding of ecophysiological vegetation and soil-moisture factors, and our understanding of landscape evolution and the role played by inheritance and antecedent conditions. Important questions to be resolved include the significance of a long-term drying trend in monsoon lake records over the past 300 ka and the resolution of unequivocal winter-westerly records through stage 5. This latter question would be addressed by long records in lakes of southwestern Australia and extended records below the LGM paleosols of Western Victorian crater lakes.

This article deals with lake-level studies from South and Central America, as far north as Mexico (i.e., Latin America). This vast area extends from the mid-latitudes of the Southern Hemisphere (more than 50° S) to the subtropics of the Northern Hemisphere (about 30° N; [Figure 1](#)). At its core lie the Neotropics, which today are dominated by summer rainfall regimes associated with the seasonal migration of the intertropical convergence zone (ITCZ) and monsoon-type circulations such as the South American summer monsoon (SASM) and the Mexican (or North American) monsoon. At higher latitudes, the influences of the subtropical high and the midlatitude Westerlies both become important. The region is also strongly influenced by the El Niño-Southern Oscillation (ENSO) driven by changes in sea surface temperatures and pressures in the tropical Pacific Ocean. Climate change studies have focused on identifying the importance of insolation forcing (millennial timescales), Northern Hemisphere conditions (ice sheets, temperatures in the North Atlantic which might lead to synchronous climate change), and the tropical Pacific (ENSO). The impact of such forcings on the location of the ITCZ, the strength of monsoons, and the position of the Westerlies all underpin the interpretation of lake-level records in paleoclimatic terms. There has also been increasing realization that climatic change and cultural change may be interlinked.

Background

Much of the early work in South America focused on the history of the Amazon rain forest, in particular whether the diversity of species in the basin reflected climatic stability or variability. A key to this was to understand the nature of climatic change during the Last Glacial Maximum (LGM; 21 000 cal years BP or 18 000 ¹⁴C years BP) and whether this change had fundamentally altered the distribution of humid tropical forest. All the early studies of lake sediment sequences in tropical South America were palynological, using vegetation change as an indicator of climate. As a result of the dominance of pollen analysis, the reconstruction of lake-level change as an indicator of changes in water balance (precipitation–evaporation) was, at best, a secondary goal and often not considered directly. Early interpretations of a dry glacial Amazon were based on geomorphological evidence, but [Liu and Colinvaux \(1985\)](#) published the first pollen record from the Amazon (Mera, Ecuador) with a full glacial radiocarbon age. These authors suggested that the glacial Amazon was significantly cooler and drier, but not arid. In contrast, the Dutch group of Thomas Van der Hammen and his collaborators, working in Colombia, also used pollen analysis to suggest that the Amazon was significantly drier and that much of the tropical forest had been replaced by savannas (e.g., [Van de Hammen, 1974](#)). Palynology has continued to dominate studies of the Amazon basin and the surrounding dry forest areas,

although now more often complemented by other proxies such as pigment analysis, carbon isotopes ($\delta^{13}\text{C}$), and diatom analysis, although siliceous microfossils are often poorly preserved in Amazonian sediments. Palynology has also dominated paleoenvironmental studies in Central America, where a number of Holocene records have been interpreted as reflecting human impact rather than climatic change.

More traditional lake-level studies, based on paleolimnological methods, have become more of a focus since the 1980s. It is also worth noting that the increasing use of core loggers and scanners is enabling data collection at unprecedented resolution, allowing the identification of high temporal-scale variability and cyclicity in records based on large datasets. Across Latin America as a whole, however, intensive lake-level studies have been limited to relatively few areas such as the Bolivian and Chilean Altiplanos, the Yucatan peninsula (Mexico and Guatemala), and the central highlands of Mexico ([Figure 1](#)). Glacial and Holocene lake-level records across the Americas were reviewed by [Bradbury et al. \(2001\)](#) and [Fritz et al. \(2001\)](#). [Vimeux et al. \(2009\)](#) provide a wide-ranging review of climate change in South America since the LGM, including lake-level data. Bradbury et al.'s review confirmed the picture of generally dry (and cool) conditions in tropical latitudes around the LGM and into the Late Glacial. In low-lying areas such as the Yucatan peninsula, this climatic drying was exacerbated by low glacial sea levels which resulted in a fall in regional groundwater levels and hence desiccation of a number of lakes dependent on groundwater inputs to maintain them ([Hodell et al., 1995](#)). The summer rainfall regimes, especially in the Northern Hemisphere tropics, were significantly diminished ([Leyden et al., 1994](#); [Metcalfe et al., 2000](#)). Reduced tropical sea surface temperatures, a lack of summer heating over continental North America (much of which was covered by the Laurentide Ice sheet), a cold North Atlantic, and reduced Northern Hemisphere summer insolation, all played a part. At a number of sites, the Late Glacial appears to have been drier than the full glacial (see Section 'Regional Examples'). The magnitude of precipitation change in the Southern Hemisphere tropics, particularly toward their southern margin where the effect of maximum summer insolation at the LGM would have been strong, is less clear. This is discussed further in the Section 'The Bolivian Altiplano'. Furthermore, long speleothem records from southern Brazil have made a major contribution to our understanding. In the Northern Hemisphere, the Laurentide ice sheet apparently split the jet stream, driving the Westerlies south, bringing increased winter rainfall to the subtropics and parts of the tropics. This resulted in the formation of extensive paleolakes in the southern part of the Basin and Range province, which extended south at least into parts of central Mexico ([Bradbury et al., 2001](#)). The exact extent of this southward migration of the Northern Hemisphere Westerlies, or increased winter precipitation due to more frequent cold fronts, is still unclear, but it may even have reached as far as Guatemala

Figure 1 The study area showing the present-day average of locations of the ITCZ in July and January, the locations of the regional examples, and other key sites referred to in the text.

(Hodell et al., 2008). In the Southern Hemisphere, whether the Westerlies tracked poleward or equatorward has been the subject of intensive debate. A review of lake data from South America south of the Tropic of Capricorn (Piovano et al., 2009) highlights the presence of two climatic regimes in southern South America, separated by the ‘Arid Diagonal,’ with the influence of the SASM to the north and east (the area of the Pampean Plain), and the Southern Westerlies to the south and west (Patagonia). The authors report that results from Salina de Bebedero (33° S, currently within the Pampean plain climatic regime) indicate several Late Glacial high stands in response to the equatorward displacement of the Westerlies and increased snow melt from the Andes. From about 13 500 cal BP into the early to mid-Holocene, high lake levels across the Pampean Plains are attributed to a strengthening of the SASM (see Section ‘The Bolivian Altiplano’).

Holocene lake-level records for Latin America are more numerous and generally better dated than those extending back to the full glacial. Sites in the Northern Hemisphere show a broadly coherent pattern of rising levels in the early Holocene as strong summer precipitation became established in response to insolation forcing, the final collapse of the Laurentide ice sheet, and sea-level rise. There are a few exceptions, however, such as La Yeguada in Panama (Bush et al., 1992). At many sites, wet conditions persisted throughout the mid-Holocene, with drying and more variable conditions setting in about 3000 years BP. In the late Holocene, the impacts of both climate and humans on lake catchments have to be taken into account. Some of the most detailed Holocene records come from the Yucatan peninsula and these are discussed below. In the Southern Hemisphere, there are fewer records, and specific lake-level studies are highly concentrated

in the region of the south central Andes (the Altiplano areas of Bolivia, southern Peru, and northern Chile). There are an increasing number of paleoenvironmental reconstructions from areas such as northeastern Brazil, but these are largely based on pollen records. In the Altiplano, the early Holocene was wet with marked drying then setting in through the mid-Holocene (e.g., Wirrmann and de Oliveira Almeida, 1987). This view of dry mid-Holocene conditions has been challenged in the literature both for the south central Andes and for southern South America more generally and is discussed further in the Section 'The Bolivian Altiplano'. By about 3000 ^{14}C years BP, however, there is evidence for wetter conditions in the Altiplano and southern Amazonia, which have been attributed to the insolation-driven southward migration of the ITCZ, the reverse of conditions in the Northern Hemisphere. There are fewer lake-level records from southern South America, but data from Lago Cardiel in Argentinian Patagonia indicate that the modern southern Westerlies became established at this latitude (49°S) by the early Holocene, following a dry, very Late Glacial (Markgraf et al., 2003). Although there is evidence for changes in the intensity of the Westerlies, Lago Cardiel does not seem to have fallen below its present level over the Holocene.

Within the broad picture outlined above, individual studies, or numbers of studies within the same area, raise particular questions or highlight specific issues. The regional examples below illustrate some of these.

Regional Examples

The Central Highlands of Mexico

Volcanic activity, mainly during the Quaternary, resulted in the formation of the central highlands of Mexico (at about 19°N) and a large number of lake basins, many of which still contain water. Lake sediment studies began quite early (Hutchinson et al., 1956), but were not undertaken extensively until the 1980s. Data from Mexico were reviewed by Metcalfe et al. (2000). Most of the records cover only the Late Glacial and Holocene and are of relatively low resolution. In this area, conditions at the LGM are still not clearly established and there are no records covering a full glacial cycle. Tephra deposition and long-term human impact also complicate the interpretation of the records.

The Basin of Mexico lies within the central highlands at about $19^\circ30'\text{N}$, at an elevation of 2240 m. It is surrounded by mountains, with peaks over 5000 m high; the volcanoes Popocatepetl and Iztaccíhuatl have permanent snow and ice fields today. The basin was formerly occupied by a series of lakes draining toward the central Lake Texcoco at about 2236 m. It has a long history of human settlement and was the site of the Aztec city of Tenochtitlan, now Mexico city. The hydrology of the basin has been completely disrupted by human activity including deep drainage, excavation of an artificial outlet, and abstraction of groundwater to supply Mexico city. The basin has been the focus for a number of lake-level studies, but these are generally poorly dated, discontinuous, or difficult to interpret due to occasional inputs of glacial meltwater (in the south of the basin), periodic desiccation, and apparently conflicting evidence from different proxies (Bradbury, 1989; Caballero et al., 1999). Prior to the LGM

(~35 000), the basin was apparently occupied by an extensive but shallow lake with marshlands. Conditions were drier around the LGM, although the intensity of this is not clear. Whether increased winter westerly precipitation reached the Basin of Mexico is disputed, but now seems unlikely. The Late Glacial was, however, very dry, with the subbasins becoming isolated and showing individualistic behavior. Texcoco and Tecocomulco (in the north of the basin) apparently both desiccated. Dry conditions persisted into the early Holocene and there is only modest evidence for increased moisture in the south of the basin around 6000 BP. Late Holocene sediments are not preserved as a result of deflation, so recent change is not recorded.

There are no well-dated, long lake-level records from Mexico, although diatom records have been published from long cores from the Basin of Mexico (Bradbury, 1971) and from Lake Cuitzeo (to the west of the Basin of Mexico). Recent deep drilling of the Basin of Mexico should provide more detailed records of long-term climate change in due course. The Cuitzeo record may extend back more than 120 000 years, but only the top 9 m of the sequence is dated. The last interglacial was probably wetter than present, as was the mid-Pleistocene. Around 35 000 BP, the lake was very low, but it then deepened around the LGM, in contrast to the Basin of Mexico. Conditions in the Late Glacial are unknown, as this part of the sequence is missing. Very low lake level is indicated around 5000 BP, which is part of a North American pattern of mid-Holocene aridity that is not evident further south. The lake has been shallow and increasingly saline over the last 3000 years, a trend which is also apparent in $\delta^{18}\text{O}_{\text{calcite}}$ data. Relatively few of the lakes in the central highlands deposit carbonate, which is suitable for the conventional $\delta^{18}\text{O}$ analysis done at Cuitzeo, but some sites deposit very diatom-rich sediment which is suitable for $\delta^{18}\text{O}_{\text{diatom}}$. Unfortunately, results to date using $\delta^{18}\text{O}_{\text{diatom}}$ have been difficult to interpret and are not discussed further here.

There has been increasing focus on recent change, using a variety of proxies to identify both human and climatic effects and attempts to integrate paleolimnological records with information from the Mexico's large Hispanic archives and more limited instrumental records (e.g., Metcalfe et al., 2010). Increased climatic variability over the last 3000–4000 years is evident in many records from the central highlands and there is emerging evidence that dry periods may show the same periodicities of Bond cycles in the North Atlantic. A major dry period is recorded around 1000 BP (the Late Classic of Mesoamerican archaeology). In the central highlands, however, this dry period was less severe than the mid-Holocene. The application of a wider range of dating methods (such as ^{210}Pb) has also allowed investigation of more recent climatic variability, including the impact of the 'Little Ice Age' (LIA). It is apparent that the expression of this period is complex, with evidence from the central highlands of conditions both wetter and drier than present, although drier seems the more widespread response.

The Yucatan Peninsula

This lowland area of predominantly limestone geology includes parts of Mexico, Belize, and Guatemala (Figure 1). Work here was pioneered by Cowgill et al. (1966) and

continued by Edward S. Deevey, who spent many years trying to find lake deposits that extended back into the LGM (see Section 'Background') and to establish how climate, humans (in this case the Maya), and environment had interacted (Deevey et al., 1979). Before accelerator mass spectrometry (AMS) dating, obtaining reliable radiocarbon dates from bulk sediments was also problematic. Palynology was the main tool of early studies, but stable isotope analysis has produced the most detailed lake-based records for this region. So far, only three lakes have yielded records extending back to the LGM, all in Guatemala: Quexil, Salpeten (Leyden et al., 1994), and Petén Itzá. Lake Petén Itzá (16°55'N), with a maximum water depth of 160 m, is the deepest lake in the region. Seismic survey has revealed a shoreline 56 m below the modern lake that formed at the end of the last glaciation, indicating an 87% reduction in water volume (Anselmetti et al., 2006). This magnitude of lake level fall explains why few other sites in this region contained water in the Late Glacial. Petén Itzá clearly has the potential to produce the longest records from this part of the Northern Hemisphere American tropics and has been cored using the GLAD800 drilling system (<http://www.dosecc.org>). Hodell et al. (2008) have published a record from Petén Itzá covering the last 85 000 years, based on core logging for density and magnetic susceptibility, pollen analysis, and a significant number of radiocarbon dates over the last 40 000 years. Unlike previous studies, this work indicates that the period of the LGM was marked by the presence of a deep lake and pine-oak vegetation, indicative of cool and moist conditions. Reduced evaporation and an increase in winter precipitation may be the explanation. Generally, conditions in the Peten were dry when the ITCZ was displaced south of its current position. On short timescales, such a southward migration of the ITCZ occurs during Heinrich events, when the North Atlantic cools abruptly and the Atlantic meridional overturning circulation slows down. Heinrich events 1–4 (H1–H4) and the Younger Dryas (sometimes referred to as H0) are recorded over the last 40 000 years of the record.

A number of detailed reconstructions of late Holocene lake-level change have been published from the Yucatan peninsula. Lake Chichancanab (Mexico) has yielded records of increasing resolution from the original stable isotope study of Covich and Stuiver (1974) to a high-resolution study of the last 2800 years. The pattern of late Holocene change in Chichancanab has been identified as showing periodicities (208 years) consistent with solar forcing (Hodell et al., 2001). Similar solar cycles have been identified in marine cores from the Cariaco basin off northern Venezuela. One of the strongest features of the Yucatan records is a series of major droughts at the end of late Classic (ca. AD 900), which coincided with the collapse of the Maya civilization. This is discussed in more detail in Section 'Climate and Culture'. In this region, it appears that the LIA was drier than present, consistent with the effect of North Atlantic cooling recorded during the LGM and Heinrich events.

The Bolivian Altiplano

The Bolivian (and Peruvian) Altiplano is a high-altitude valley (average elevation about 4000 m) within the central Andes (Figure 1). The valley is occupied by a series of lakes or salt flats (salars) which have shown varying degrees of hydrological

integration over the Pleistocene. Lake Titicaca is the highest of the basins (3810 m) and most northerly, overflowing to the south through the Rio Desaguadero into Lake Poopo. The Salar de Uyuni (3653 m) is the most southerly of the lake basins, where drilling has revealed a long sequence of alternating lacustrine clays (wet) and salt deposits (dry). The site of the Quelccaya ice core lies to the north, while that of the Sajama ice core is the western Cordillera between Titicaca and the salars (for details see <http://www.ncdc.noaa.gov/paleo/ice-core.html>). The integration of glacial, ice core, and lake records has been an important element of work in the Altiplano. A number of papers on the area have been brought together by Seltzer et al. (2003). Early studies reported the existence of a major deep lake phases in the Late Glacial, together called the Taucu phase, when Titicaca was deep and overflowing and Taucu was also deep (up to 142 m according to Fornari et al., 2001). The timing of the start of the Taucu phase was extended back to before the LGM (to ~26 000), for details see Baker et al. (2001). The identification of wet conditions at the LGM sets this area apart from the Northern Hemisphere tropical Americas and also implies that Amazonia must have been wet as it (with the Atlantic) is the main source of precipitation for the Altiplano. The implication is that the SASM remained strong, driven by the southward displacement of the ITCZ and stronger summer insolation. A link between wet conditions on the Altiplano and cold sea surface temperatures in the North Atlantic has been proposed. The enhancement of the SASM during the LGM, and coincident with Heinrich events in the North Atlantic, has been supported by long speleothem records from southern Brazil, primarily from Caverna Botuverá (Wang et al., 2007). As described above, however, the records from Amazonia generally point to drier conditions, or perhaps little change from present. There are very few records from southern Amazonia, but Mayle et al.'s (2000) pollen records from lowland eastern Bolivia (Laguna Bella Vista and Laguna Chaplin) indicate dry conditions in the full and Late Glacial.

Although the transition from the glacial into the Holocene was complex (Baker et al., 2001), lake levels fell in the early Holocene, and by 6000–5000 BP Titicaca was apparently some 85 m below its present level, the lowest of the last 25 000 years. This pattern of mid-Holocene aridity was apparently widespread in the Bolivian and Chilean Altiplano as well as in southern Amazonia. The pattern of drying from the early Holocene is the opposite of that in the Northern Hemisphere tropics and can be explained by the reduced summer insolation and the northward displacement of the ITCZ.

As described in the Section 'Background', however, the ubiquity of a dry mid-Holocene across southern South America has been challenged. It has been suggested that one of the reasons for the differences of opinion may relate to the varying response times of different proxies (Grosjean et al., 2003). However, the relative sparseness of records across a very large area must be considered, and the more abundant records from the northern tropical Americas illustrate the spatial and temporal complexity of Holocene change. Lake levels in the Altiplano recovered in the late Holocene and Titicaca has been generally high, except for four drier intervals, over the last 3000 years.

The Altiplano is starting to yield some long records of change due to deep drilling in the Salar de Uyuni, the valley of the Desaguadero, and Titicaca itself, using the GLAD800 coring system (<http://www.dosecc.org>). These have confirmed

the occurrence of multiple wet phases on the Altiplano over the mid- and late Pleistocene. There seem to be different trends in the northern and southern Altiplano, with the lake levels during wet periods getting progressively higher in the south and lower in the north, possibly due to changes in the height of the outlet of the Desaguadero. It also appears that the conditions of the LGM and Holocene are not typical of previous glacial and interglacial stages, which has implications for the identification of climatic forcings (Fritz et al., 2004).

ENSO Records

As described above, the modern climate of South America is particularly strongly affected by ENSO, which brings much wetter than normal conditions to areas of the west coast (e.g., coastal Peru and Ecuador) and drier than normal conditions to areas such as north east Brazil. (For more details regarding ENSO, see <http://www.esrl.noaa.gov/psd/ENSO/>.) To date, there are few lake sediment records from South or Central America (including Mexico) of sufficiently high resolution (annual or subannual) to capture ENSO signals; our understanding of ENSO is based largely on records from corals, high-resolution marine cores, and tree rings. There are ENSO records from laminated (or mainly laminated) lake sediments, from Laguna Pallcacocha in the Andes of Ecuador and Bainbridge and El Junco crater lakes in the Galapagos Islands. In both areas, El Niños are marked by increased precipitation. At Pallcacocha, El Niño events are marked by layers of clastic sediments produced by increased runoff (Rodbell et al., 1999), while, at Bainbridge Crater, clastic layers are thought to represent very intense El Niños and carbonate layers moderate events which lower the lake's salinity but do not generate a lot of catchment erosion. A similar distinction between rainfall amount (silt/clay) and intensity (sand) is made at El Junco. The records show that the frequency and strength of ENSO events increased over the Holocene, reaching modern periodicities about 7000 BP and very clearly from 5000 to 4000 BP. Strong El Niños have become more common. Pallcacocha and Bainbridge also record millennial-scale variability in ENSO, which may be the result of the system's internal dynamics rather than external forcing (Moy et al., 2002). It seems likely that there are other lake basins in Latin America depositing lake sediments which could yield paleo-ENSO records. The impact of ENSO-type variability, particularly over decadal to centennial timescales, is of increasing interest, although identifying the forcing mechanisms for these is complex.

Climate and Culture

Although one has to be cautious about attributing cultural change to climatic variability, there is paleolimnological evidence from a number of sites in South and Central America to suggest that persistent drought conditions have been important in driving change in human societies (Brenner et al., 2001). A key area for this has been the Yucatan peninsula (see Section 'The Yucatan Peninsula') which lay at the heart of the pre-Hispanic Maya culture. Around AD 900, major building projects apparently ceased and a number of large settlements were abandoned, which has come to be called

the Maya 'collapse.' Given the problems of water storage and access in limestone geology and a variable climate, it had been hypothesized that drought may have played a part in the late Classic collapse. Hodell et al.'s (1995) paper on Chichancanab (see Section 'The Yucatan Peninsula') provided the first unequivocal evidence for drought in the late Classic, although the sampling and dating resolution were not high. A more detailed record from Lake Punta Laguna (Mexico) confirmed the late Classic drought, but also indicated that the droughts had multiple peaks and had become progressively more intense (Curtis et al., 1996). Prior to the collapse, an earlier series of droughts could be associated with the Maya hiatus. The complexity of the drought signal has been confirmed both by the marine Cariaco core (see Section 'The Yucatan Peninsula') and by a higher resolution study from Chichancanab based on bulk density data (Hodell et al., 2005). It should not be assumed, however, that all lake records in the Yucatan record a major drought in the late Classic; some lakes do not, either because they are large enough for their water balance not to be significantly affected, or because the spatial extent of the drought was probably variable. There is some evidence for late Classic drought in the central highlands of Mexico (see Section 'The Central Highlands of Mexico'), but here it was apparently less intense except perhaps on the drier northern margin of the highlands where some catchments may have been abandoned.

There is also lake-level evidence for drought affecting pre-Hispanic cultures in the central Andes. The best documented case relates to the Tiwanaka culture that occupied the area around Titicaca from about AD 600, but collapsed about AD 1150 at the same time as drought conditions are recorded in a core from Titicaca (and in the Quelccaya ice cap). This drought period has also been recorded in the area around Cuzco (Peru), where many pre-Hispanic drought periods correspond to important cultural changes (Chepstow-Lusty et al., 2003 or <http://antiquity.ac.uk/ant/085/ant0850570.htm>).

Introduction

Stratigraphic records of lake-level change are important for reconstructing the hydrologic budget of the past. They provide a clearer picture of long-term hydroclimate variability than instrumental records, which in North America are typically shorter than 150 years, and they complement other long-term records of changes in terrestrial moisture budgets, such as dendroclimatological, palynological, and charcoal records. In western North America, dramatic changes in the climate and landscape during the late Pleistocene and Holocene produced variations in lake level of 10s to 100s of meters (Benson, 2003). The geological evidence of this variation includes former lake shorelines where no lakes currently exist, deltas evident in subsurface geophysical surveys where rivers previously entered vast lakes, and massive flood-formed landforms that were the result of the release of water from ice-dammed lakes in regions currently without continental ice sheets. From the spectacular records of the release of meltwater from glacial ice-dammed Lakes Agassiz (Teller et al., 2002) and Missoula (Peterson et al., 2011) to the rapid drainage of the extensive pluvial Lakes Lahontan and Bonneville (Benson, 1978; Oviatt, 1997), to the more subtle variation embedded in the sediments of small glacial lakes (Williams et al., 2010), records of lake-level change have played an important role in identifying and developing our understanding of Quaternary climate change in North America (Figure 1; Table 1).

Each lake is defined by a unique set of physical, chemical, and biological parameters that determine how it responds to the dynamics of external drivers, such as changes in climate. A substantial change in any of the major climatic variables that affect a lake's water budget, for example, a change in precipitation, runoff, evaporation rate, or groundwater flow can effect a change in lake level (Fritz, 2008). The influence of these external climate drivers is modulated by the size and morphology of a lake basin and its watershed, which determine the rate and magnitude of the lake's response to changes in hydrologic variation and the nature of the climate signature recorded in the basin. Small lakes typically function somewhat like individual climate stations tracking local conditions that are superimposed on long-term patterns of climate change, whereas larger lakes tend to integrate the influence of the hydrologic budget of a broader region (Shuman et al., 2002; Williams et al., 2010). In addition, some regions are more sensitive to certain aspects of climate variability, such that even small changes in effective moisture can produce profound changes in lake level.

Inferring the drivers of lake-level change and the magnitude of their variation from paleolimnological records can be challenging because of the complex influences of hydrogeomorphic setting on a lake's hydrologic budget (Fritz, 2008).

Many paleolakes have shown marked fluctuations in lake level during the Pleistocene and Holocene in response to capture or diversion of influent rivers rather than climate (Benson and Paillet, 1989; Bradbury et al., 1989; Kaufman et al., 2009; Kowalewska and Cohen, 1998). Landscape position also affects the nature of lake-level change in response to external drivers. For example, in kettle lakes connected by a shallow aquifer, the magnitude of lake-level lowering can be strongly influenced by the distance between the lake and the base level of the river system that drains the watershed (Digerfeldt et al., 1993); therefore, regionally, lake-level lowering in response to aridity might be greater in lakes farther from rivers. In dune-dominated landscapes, hydrologic response to drought can be quite complex. In some regions of the Nebraska Sand Hills, blockage of paleovalleys by migrating dune sand during the late-Glacial and Holocene periods caused a rise in the regional water table (Loope et al., 1995; Mason et al., 1997). In interdunal wetlands above the dune dams, water levels aggraded, producing lake-level rise during intervals of extreme aridity.

To some extent, a network of sites can depict the dominant patterns of lake-level variation in response to climate and can circumvent the variable influences of hydrogeomorphic setting. A North American lake-level database, largely derived from sedimentological and palynological data, has been used to examine patterns and rates of lake-level change in the eastern and Midwestern parts of the continent following the retreat of the Laurentide Ice Sheet (Shuman et al., 2002; Williams et al., 2010). In the Midwest, for example, the impact of site-specific factors is clearly evident in the varied lake status in any given time slice (Figure 2), yet the central tendency was one of declining lake levels as climate dried from the early to mid-Holocene. At the majority of sites, the rate of change was most rapid at 8 cal ka BP (Williams et al., 2010), which suggests the combined influence of the collapse of the Laurentide Ice Sheet and high summer insolation in driving lake-level decline.

Regional Lake-Level Histories

The Northern Great Plains and Midwestern North America

Glacial Lake Agassiz is undoubtedly the most significant lacustrine lake-level record from north-central North America. Lake Agassiz was an enormous ice-dammed lake that formed at the southern margin of the Laurentide ice sheet during the last deglaciation. At ~13 cal ka BP, it was the largest lake in North America (NA) (>400,000 km²), and changes in the routing of its drainage are posited to have played a major role in affecting both regional and global processes (Teller et al., 2002). The lake-level history is delineated by several strandlines formed at high lake stages separated by intervals of lowered lake level. The lowered levels resulted from rapid drainage

Figure 1 Sites of lake-level studies in North America discussed in the text. Number locations are keyed to the references listed in [Table 1](#).

of large volumes of water as the southern margin of the Laurentide ice sheet retreated and exposed new outlets. Rapid outbursts of glacial meltwater into the North Atlantic have been hypothesized to have affected meridional overturning circulation and produced widespread and rapid climatic change, including the Younger Dryas interval, the Preboreal Oscillation, and the 8.2 climate event (Clark et al., 2001). However, the chronology of drainage, the specific locations of outlets, and hence the role of Lake Agassiz in affecting the observed climate events is controversial (Fisher et al., 2008; Murton et al., 2010). The Laurentian Great Lakes themselves also

show a dramatic history of lake-level change during deglaciation and the Holocene that reflects of the complex interplay of climate, glacial meltwater inputs, and isostatic adjustment (Clark et al., 2011; Colman et al., 1994). Higher frequency lake-level variation in the late Holocene interval may be more clearly linked to climate than the fluctuations of prior periods (Wilcox et al., 2007).

The majority of other lacustrine records in the northern tier ($>40^{\circ}\text{N}$) of the NA continental interior are from smaller lakes that were formed by retreat of the Laurentide ice sheet; thus stratigraphic records from these sites span the terminal

Pleistocene and the Holocene. In the northern Great Plains, a grassland region to the east of the Rocky Mountains, lake-level variation commonly has been inferred from reconstructions of salinity, ionic composition, and isotopic variation rather than proxies of lake level itself. Here, freshwater conditions persisted from the onset of lake formation into the early Holocene, suggesting high lake levels and abundant precipitation. High salinity in the mid-Holocene was followed by lowered salinity in the late Holocene, suggesting a shift from low lake levels and arid climate to higher lake levels during the cooler, drier conditions of the last 3–4 cal ka (Laird et al., 1996; Schwalb and Dean, 1998; Smith et al., 2002). In the forested areas of the Midwest, from the modern forest-prairie border to the western Great Lakes region, lake-level reconstructions have been derived from paleolimnological, pollen, and sedimentological data, including transects of cores (Figure 3; Digerfeldt et al., 1993; Filby et al., 2002; Harrison and Metcalfe, 1985; Winkler et al., 1986). Here Holocene patterns of lake-level and inferred climate variation are similar to those inferred from the northern Great Plains, although the timing of onset of mid-Holocene aridity is commonly somewhat later than in sites further west (Fritz et al., 2001). The high lake levels and effective moisture of the early Holocene throughout the northern Great Plains and Midwest, at a time when summer insolation also was very high, likely reflects the downstream effects of the remnant Laurentide ice sheet, which persisted in northern Canada until ~8 cal ka BP. Similarly, the onset of mid-Holocene aridity in the interior is probably linked to ice-sheet collapse and the associated abrupt drainage of Lake Agassiz at ~8.4 cal ka BP (Williams et al., 2010).

The Great Basin

Throughout the Pleistocene, the Great Basin was occupied by dozens of large pluvial lakes (Benson and Thompson, 1987; Gilbert, 1890; Russell, 1885), whereas today just a few permanent lakes remain. The two largest of these lake systems were Lake Bonneville, which at its maximum extent covered more than 50,000 km² and was more than 370 m deep, and Lake Lahontan, which covered more than 22,000 km² and was more than 275 m deep. Early work focused on the timing and correlation of physical evidence of shorelines from former Lakes Bonneville and Lahontan in the subsurface or exposed in outcrops (Benson, 1978; Oviatt et al., 1992; Smith and Street-Perrot, 1983), while subsequent research has coupled this approach with continuous high-resolution stratigraphic records of past lake level from persistent or remnant lakes, inferred

Figure 2 Lake-level sites and plant taxa distributions for eastern North America. Lake levels dropped in the central US between 10 and 7 ka, but rose in other regions, indicating that moisture-balance variations differed by region. The lake-level data generally match with palynological evidence for an eastward advance of the prairie–forest boundary during the early Holocene and increased abundances of mesophytic (relatively moisture-loving) taxa (beech, *Fagus*, hemlock, *Tsuga*, and southern species of pine, *Pinus*) in the eastern US; northern species of pine (*Pinus*) prefer drier conditions than beech and hemlock. Note that symbols in the upper panels indicate whether lake-level changes were inferred from core transect studies, qualitative interpretations of data from single cores, or from sedimentary hiatuses in single cores. Data from Shuman et al. (2002).

from changes in fossil diatom and ostracode assemblages, pollen and macrophyte assemblages, sedimentology, isotopic composition, other geochemical variables, and grain size (Adams, 2007; Bacon et al., 2006; Benson, 2003; Benson and Thompson, 1987; Bradbury et al., 1989; Cohen et al., 2000; Kaufman et al., 2009; Li et al., 2008; Negrini et al., 2006).

The longest records from the lakes of the Great Basin express a rich lake-level history through the Quaternary, with multiple prolonged periods of lake expansion and contraction. Often change was asynchronous among basins as lakes spilled over, downcut through topographic divides, and coalesced (Benson and Thompson, 1987). The influx of moisture for lakes in the Great Basin is strongly influenced during the cool seasons by the polar jet stream, which carries moisture from air masses sourced in the North Pacific. Throughout the late Pleistocene, persistent changes in the inferred position and intensity of the polar jet stream were associated with changes in the global ice volume, providing a teleconnective link between glacial–interglacial cycles, large-scale ocean–atmospheric processes, and observed long-term regional patterns in lake level from Pyramid, Owens, Summer, Mono, Great Salt, and Bear Lakes (Balch et al., 2005; Benson et al., 2003; Kaufman et al., 2009; Oviatt, 1997; Patrickson et al., 2010). Leading into the Last Glacial Maximum (LGM), the records from most of the lakes of the Great Basin indicate a gradual rise in lake level, reaching the most recent highstands between 16 and 13 cal ka BP (Benson and Thompson, 1987). Between 13 and 10 cal ka BP, the lake-level response to climate was much more variable among basins, but overall the records indicate declining lake levels.

By 12–10 cal ka BP, most of the pluvial lakes of the Great Basin were largely reduced to remnant lakes or had disappeared entirely.

Similar to the record from the Northern Great Plains, the early Holocene was a period of widespread increase in effective moisture, with a broadly coherent pattern of increasing the lake level throughout most of the Great Basin. Many modern lakes in the region reached their Holocene maximum highstands when summer insolation was high (Figure 4), between 10 and 7.5 cal ka BP (Bacon et al., 2006; Bird et al., 2010; Kirby et al., 2010; Smoot and Rosenbaum, 2009), but declined rapidly in the mid-Holocene to near-desiccation levels in a period centered around 5 cal ka BP. After 3.5 cal ka BP, most lakes in the Great Basin began to rise again, although fluctuating around lake levels persistently lower than the early Holocene. Highly detailed physical records of lake-level change from truncated deltas and former shorelines exposed in outcrop, sedimentary structures in sediment cores, and death dates on drowned trees have provided unequivocal evidence of significant lake-level change throughout the late Holocene from the Mono, Tulare, and Walker Lake basins (Adams, 2007; Negrini et al., 2006; Stine, 1990, 1994), including prolonged drought during Medieval times.

The Rocky Mountains and Southern Canadian Cordillera

The mountainous western part of North America is an arid to sub-humid region speckled with numerous small and moderate-sized, shallow to deep lakes, many in

Figure 3 (a) Ground-penetrating radar (GPR) profile and (b) images of transect cores from Hidden Lake in northern Colorado. (c) An aerial photo shows the location of the GPR profile, which contains a bright reflector indicative of a paleoshoreline (and sedimentary unconformity) near the western shore of the lake. Dashed lines highlight the same feature in the core images. The stratigraphic evidence indicates that water levels were likely several meters lower than today during the mid-Holocene. Data from [Shuman et al. \(2009\)](#).

hydrographically closed basins. However, the heterogeneous terrain and large elevational gradients among sites often result in spatially complex patterns of climate. At the time of the LGM, most of this region was overlain by continental ice sheets and mountain glaciers, so many lake archives in the region typically span the last 16 cal ka BP or shorter, depending upon the timing of regional deglaciation. Prior to deglaciation, classic ice-dammed lake sites, such as Glacial Lake Missoula, underwent multiple sequences of substantial changes in lake level as a result of outburst flooding ([Pardee, 1910](#); [Peterson et al., 2011](#)).

[Walker and Pellatt \(2008\)](#) produced a comprehensive analysis of 61 lake records from the area around the Columbia Basin, which included evidence of lake-level changes from Big, Mahoney, Kilpoola, Burnell, Fir, and Valentine Lakes inferred from pollen and paleosalinity reconstructions from fossil chironomid and diatom data. The analysis showed that the timing and direction of lake-level change varied greatly between individual lake basins. For example, the records from Big and Burnell Lakes indicate significant low stands between 9 and 6 cal ka BP, whereas nearby Mahoney Lake has a nearly diametric pattern, with a substantial drop in salinity centered at 7 cal ka BP.

In the Northern Rockies of the United States, changes in lake level and effective moisture have been reconstructed from

fossil diatom assemblages, oxygen isotopes, and multiple-core transect stratigraphy coupled with subsurface geophysical surveys. Evidence from a 14-cal ka BP record from Foy Lake, Montana ([Figure 5](#)) indicates that lake levels fluctuated substantially during the deglaciation and into the early Holocene, yet were lower than today ([Shuman et al., 2009](#); [Stone and Fritz, 2006](#)). A substantial drop in lake level occurred between 7 and 3 cal ka BP, evidenced by changes in fossil diatom and sedimentology, and lakes rose substantially after 3 cal ka BP, reaching the highest stage in the last 1.5 cal ka BP ([Shuman et al., 2009](#); [Stevens et al., 2006](#); [Stone and Fritz, 2004](#)). This pattern matches regional changes in effective moisture reconstructed from oxygen isotopic records from Jones Lake, Montana in the neighboring Ovando Valley of Montana ([Shapley et al., 2009](#)) and the broad pattern of the changing lake level from extensive multiple core and seismic profile studies of nearby Flathead Lake ([Hofman et al., 2006](#)).

Mid-Holocene lowstands also have been identified in the Central and Southern US Rockies. The records of Hidden and Little Molas Lakes in Colorado ([Figure 5](#)) show low lake levels from 7 to 4 cal ka BP ([Shuman et al., 2009](#)), matching the general pattern of low effective moisture during this period reconstructed from oxygen isotope record from Bison Lake, Colorado ([Anderson, 2011](#)), as well as records from multiple other lakes in Arizona, Colorado, and Wyoming that show

Geological Society of America Special Paper 450.

Figure 5 Summary of regional lake level for the Rocky Mountain region. Blue lines indicate inferred changes in the lake levels at Foy, Hidden, and Little Molas Lakes; dashed lines indicate when lower-than-modern levels are inferred but poorly constrained. Numbered bars indicate the timing of low-lake stands at other locations: (1) Flathead Lake, MT; (2) Jones Lake, MT; (4) Park Pond 2, WY; (5) Forest Pond 2, WY; (6) Park Pond 1, WY; (7) Cottonwood Pass Pond, CO; (8) Red Lady Fen, CO; (9) Red Well Fen, CO; (10) Bear Lake, AZ; (11) Fracas Lake, AZ; (13) Montazuma Well, AZ; (14) Potato Lake, AZ. Modified from Shuman B, Henderson A, Colman SM, et al. (2009) Holocene lake-level trends in the Rocky Mountains, USA. *Quaternary Science Reviews* 28: 1861–1879.

evidence for low lake levels during the mid-Holocene. Weng and Jackson (1999) report unconformities in cores from the center of Fracas and Bear lakes in northern Arizona. The unconformities indicate lake desiccation between 8.5 and 2 cal ka BP at Fracas Lake and between 7.4 and 4.23 cal ka BP at Bear

Lake. In Colorado, Cottonwood Pass Pond shows evidence of transition to a mire without open water from ca. 7 to 4 cal ka BP, and several nearby fens only formed in the last 4.5 cal ka BP (Fall, 1997).

Similar to the Great Plains and Great Basin, Holocene changes in summer insolation played an important role in the regional pattern of effective moisture balance in the Rocky Mountains. Particularly in the southern Rocky Mountains, summer precipitation rates in the early Holocene may have increased under the effect of high summer insolation on the southwestern 'monsoon' (Harrison et al., 2003). The small number of high-resolution (decadal to centennial scale) Holocene records of effective moisture balance from the northern and central Rocky Mountain regions (Anderson, 2011; Shapley et al., 2009; Stone and Fritz, 2006) also show higher-frequency (decadal to centennial) changes in lake level, probably driven by ocean-atmospheric dynamics expressed in climate mode indices, such as the Pacific Decadal Oscillation and the North Pacific Index (Barron and Anderson, 2011).

Alaska and the Yukon Territory

The semi-arid interior regions of Alaska and the Yukon have low precipitation rates compared to the relatively high rates of evaporative loss (Barber and Finney, 2000), thus lakes in the region have the potential to record significant changes in hydrologic balance. Lake-level fluctuations in this region have been inferred from sedimentary evidence of desiccation, changes in pollen stratigraphy, and more recently, multiple-core transect stratigraphy (e.g., Abbott et al., 2000, 2010; Anderson et al., 2005b; Bigelow and Edwards, 2001; Brahney et al., 2008; Mann et al., 2002).

Much of Alaska and the Yukon was not glaciated during the Quaternary. Long lacustrine records from Alaska commonly indicate that the last glacial period was characterized by a widespread decline in lake level, typically expressed as an extensive hiatus between 35 and 23 cal ka BP (Abbott et al., 2010). Lake levels started to rise between 23 and 17 cal ka BP, before a widespread increase in effective moisture, evidenced by substantial changes in vegetation, resulted in a regional lake-level rise by 14–15 cal ka BP (Abbott et al., 2000; Ager, 2003; Bigelow and Edwards, 2001; Edwards et al., 2001). Lakes fluctuated substantially during the late-Glacial period, with significant lowstands; some of these are closely associated with the Younger Dryas event (Mann et al., 2002) in the western part of Alaska. Pollen and lake records for the eastern interior of Alaska suggest a gradual increase in moisture from the LGM through the mid-Holocene, reaching near-modern levels by 6 cal ka BP (Edwards et al., 2001). Records throughout the western region of Alaska suggest that lakes remained lower than modern into the early to mid-Holocene (Figure 6), then rose to reach near-modern levels by 4 cal ka BP (Abbott et al., 2000; Anderson et al., 2005b; Barber and Finney, 2000).

As with other regions of North America, aridity during the early Holocene may be related to greater summer insolation (Abbott et al., 2000; Finney et al., 2005). Several recent studies have suggested that ocean-atmosphere linkages are further mediated by solar forcing and together these features have influenced effective moisture in the Alaska and Yukon region, particularly with respect to abrupt climate transitions since the

Figure 6 Comparisons of lake-level reconstructions for lakes in interior Alaska and the Yukon Territory. Lakes were low prior to ca. 15 cal ka BP, and rose with fluctuations during the late deglacial. An abrupt lake-level rise occurred in the early Holocene (9.5 cal ka BP), though lakes remained lower than modern until the mid-Holocene. Modified from Anderson L, Abbott MB, Finney BP, and Edwards ME (2005) Paleohydrology of the southwest Yukon Territory, Canada, based on multi-proxy analyses of lake sediment cores from a depth transect. *The Holocene* 15: 1–12; The Birch Lake, Alaska, record is from Abbott et al. (2000).

LGM (Hu et al., 2003, 2006). Increased continentality resulting from the large areas of shallow adjacent continental shelves exposed during lower sea levels has also been considered as a factor contributing to lower lake levels during this period (Abbott et al., 2000). During the deglacial to early Holocene transition, changes in atmospheric circulation related to effects of the Laurentide ice sheet may have been important (Abbott et al., 2000; Finney et al., 2005). The amount of precipitation reaching the interior is strongly affected by changes in winter storm tracks, primarily driven by the semi-permanent low pressure center known as the Aleutian Low. On decadal to millennial timescales, persistent shifts in the intensity and position of the Aleutian Low throughout the Holocene may have had a profound effect on lake levels (Anderson et al., 2005a; Clegg and Hu, 2010; Edwards et al., 2001; Kaufman et al., 2010).

Northeastern North America

Lakes in the northeastern part of the continent also were formed primarily by glaciation and contain records that span the terminal Pleistocene and Holocene periods. Lake-level reconstructions across the region, derived from sedimentological data, show considerable regional variation in temporal trends, reflecting the complex interplay of multiple large-scale

influences, including the northward advection of tropical moisture, westerly storm tracks, the Great Lakes, and changes in aquifer height linked to sea-level rise, coupled with more localized factors. Multiple sites from New York north to Quebec (Dwyer et al., 1996; Lavoie and Richard, 2000; Newby et al., 2000; Shuman et al., 2001, 2005) show low lake levels in the early Holocene, but with considerable variation in the onset and termination of dry conditions. In Quebec, lake level continued to be low until ~3 cal ka BP, except for a brief interval ~6 cal ka BP (Lavoie and Richard, 2000; Muller et al., 2003). In Maine, lake level also was low in the mid-Holocene (8–6 cal year BP) but began to rise to modern levels after ~6 cal ka BP (Almquist et al., 2001). The pattern of mid-Holocene lake level in sites immediately to the south in New Hampshire (Shuman et al., 2005), Massachusetts (Newby et al., 2000, 2011; Shuman et al., 2001), and New York (Dwyer et al., 1996) differ from those in Maine and Quebec, with high lake levels and inferred wet conditions through much of the mid-Holocene, followed by lake-level lowering between ~5.5 and 3 cal ka BP, spanning the period of the eastern hemlock decline. On the western edge of Lake Ontario (Yu and McAndrews, 1994; Yu et al., 1997), high lake levels in the early Holocene resemble the patterns in the Midwest, but the onset of mid-Holocene aridity does not occur until ~6 cal ka BP, like the sites directly to the east in

Figure 7 Summary pollen, macrofossil, and loss-on-ignition diagram for Lake Tulane, FL. The black curve (right) shows the GISP2 $\delta^{18}\text{O}$ curve; the red curve (right) is the sum of *Quercus*, *Ambrosia*, and *Poaceae* pollen. The interstadials are numbered to the right of the $\delta^{18}\text{O}$ graph. The darker bars indicate the ages and time spans of Heinrich events; the yellow bars indicate the Tulane *Pinus* phases. Reproduced from Grimm EC, Watts WA, Jacobson GL Jr., Hansen BCS, Almquist HR, and Diffenbacher-Krall AC (2006) Evidence for warm wet Heinrich events in Florida. *Quaternary Science Reviews* 25: 2197–2211.

southern New England. High lake levels, in some cases the highest of the Holocene, are characteristic of the last 3–2 cal ka BP in all of northeastern NA (Webb et al., 1993a).

The low lake levels and dry conditions in northeastern NA in the early Holocene are attributed to both the high summer insolation and the influence of the glacial anticyclone at the margin of the remnant Laurentide ice sheet (Webb et al., 1993a). As the ice sheet collapsed, the higher lake levels and moist conditions in southern New England may be a product of the reduced influence of the glacial anticyclone and the resultant enhanced northward advection of subtropical moisture (Shuman et al., 2002). Increased effective moisture and lake-level rise across the northeast in the late Holocene was associated with insolation-driven increases in winter precipitation and reductions in summer temperature; the drivers of the ~5.5–3 cal ka BP period of lowered lake levels from southeastern Ontario through southern New England are less clear, but may be related to higher frequency changes in Atlantic sea-surface temperatures that affected the seasonality of precipitation (Newby et al., 2011; Yu et al., 1997).

Southeastern United States

No studies in the southeastern United States have explicitly studied lake-level history, but numerous studies of fossil pollen data have produced evidence suggesting that lake levels have changed during the late Quaternary. The region was not

glaciated, and many lakes were either sinkholes or Carolina bays, which are circular depressions of uncertain origin. The southeastern US is the one of the most humid portions of North America, but many lakes – especially in Florida – show evidence of desiccation (e.g., Watts et al., 1992). Lake drying during glacial times likely reflects a lowered groundwater table associated with low sea level. Lake basins began to fill throughout the region in the early Holocene, probably because of the rising sea level and aquifer height, possibly augmented by increased precipitation (Shuman et al., 2002). The macrophyte and pollen evidence from Lake Tulane, Florida, which extends back 60 ka, also provides compelling evidence of earlier lake-level fluctuations driven by large-scale ocean–atmospheric teleconnections (Grimm et al., 1993, 2006), marked by alternating periods of domination by oak and pine (Figure 7). Sharp increases in fossil pine pollen abundances occurred during Heinrich events and the latter half of the Holocene. In periods dominated by oak forest, enhanced deposition of organic matter occurred and shallow emergent and damp-ground macrophytes were more abundant. This suggests very shallow water and a close proximity of the core site with the shoreline.

Continental-Scale Climate Variation

The prevailing pattern throughout North America, particularly west of the Great Lakes, was high lake levels during the late

Pleistocene and early Holocene, low lake levels during the mid-Holocene, and a return to relatively high levels more recently. These long-term trends have been attributed to two major factors. First, the presence of the Laurentide ice sheet dramatically influenced regional energy budgets and atmospheric circulation patterns prior to ca. 8 cal ka BP (COHMAP, 1988; Webb et al., 1993b). The ice sheet shifted the position of the polar jet stream southward, delivering high amounts of precipitation; cool conditions associated with the ice sheet also reduced evapotranspiration in neighboring regions. However, the southward-displaced jet, plus high summer insolation, left northwestern areas dry in the late Pleistocene and early Holocene. As the ice sheet collapsed, its climatic influence diminished – decreasing precipitation as storm tracks changed and increasing evapotranspiration as conditions warmed. Second, changes in insolation strongly influenced regional energy budgets as well as atmospheric circulation patterns. Insolation became the dominant control after the influence of the ice sheet waned, and probably contributed to the dry mid-Holocene conditions through heightened evaporation rates (Webb et al., 1993b) and through continental-scale atmospheric dynamics (e.g., Harrison et al., 2003). As orbital configuration changed, insolation levels have progressively reached the low seasonal contrast of today and conditions became progressively wetter than before. The influence of higher frequency ocean–atmosphere interactions on climate and lake-level variation, particularly variation associated with Pacific Ocean sea-surface temperatures, also are evident in the small number of high-resolution (decadal) studies from western North America.

Dry early Holocene conditions in eastern North America from New England to Florida have also been explained as the result of greater-than-modern summer insolation and the atmospheric influence of the Laurentide ice sheet (Shuman et al., 2001, 2002; Webb et al., 1993a). Moisture levels increased in the southeast and then in the northeast, as indicated by lake-level rises and plant species migrations, while conditions simultaneously dried in the mid-continent. As the ice sheet collapsed, high summer insolation probably increased the influence of the Bermuda subtropical high on eastern North America, causing the northward advection of subtropical moisture (Shuman et al., 2002), while simultaneously decreasing annual moisture balance in the mid-continent.

Introduction

The water cycle is a crucial factor in climate change; variations in the hydrological cycle are a key issue in the perspective of present global warming and concerns over water resources availability. Most data collected to reconstruct past Holocene climatic oscillations preferentially document past changes in temperature. In addition to the reconstruction of past variations in fluvial discharge and water table in mires, lake basins provide interesting archives since the lake-level records make it possible to document past changes in the water budget in relation to climatic variations. After the pioneering investigations by T. Nilsson and G. Digerfeldt in Sweden, lake-level studies developed in Europe against the backdrop of (1) the IGCP Project 158B (Berglund et al., 1983; Gaillard, 1985; Ralska-Jasiewiczowa and Starkel, 1988), (2) the construction of a European Lake Status Database (Harrison et al., 1998; Yu and Harrison, 1995), and (3) the archaeological controversies on the prehistoric lake dwellings in the sub-Alpine area (Ammann, 1982; Jacomet, 1985; Lüdi, 1935; Magny, 2004a). This article presents (1) the method used to reconstruct past lake-level changes and (2) a synthesis of results obtained over the last two decades in west-central Europe to establish a regional pattern of Holocene lake-level changes. Finally, it examines their paleoclimatic significance in terms of atmospheric circulation, climatic parameters, and forcing factors.

Study Area and Method of Lake-Level Reconstruction

The study area is composed of the Jura Mountains, the northern French Pre-Alps, and the Swiss Plateau (Figure 1). This region in west-central Europe is well placed for the study of changes in atmospheric circulation patterns, particularly the position of the Atlantic Westerly Jet, which determines the latitudinal extension of the Hadley cell and the midlatitude storm tracks.

The lake-level data presented here are a compilation of records obtained from 26 lakes (Figure 1). Lake levels are influenced by climatic parameters affecting both evaporation and precipitation, but they can also be induced by a variety of local, nonclimatic factors such as geomorphological and hydrographic phenomena. In Europe, another factor may be human impact on the vegetation cover in the catchment, which could have occurred relatively early, that is, ca. 8.5–8 ka BP. The replication of records from the same area, although time-consuming, allows one to observe synchronous changes in several lakes within a region and to testify to their climatic origin (Digerfeldt, 1988; Magny, 2004b). Most of the lakes studied are characterized by a nivo-pluvial regime (highstands during autumn and spring due to rain and/or snow melting); some have a small proportion of their water furnished by glacier meltwater in summer.

Since the 1980s, different methods have been used to reconstruct past variations in lake levels in Europe, that is, stable isotope analyses (Hammarlund et al., 2003; Valero-Garcés et al., 1998), changes in assemblages of mollusks (Clerc et al., 1989), diatoms and cladocera (Hyvärinen and Alhonen, 1994; Korhola et al., 2005), and plant macrofossils (Digerfeldt, 1988; Hannon and Gaillard, 1997). Archaeological data also provide evidence of past lake levels, though this is often questionable due to uncertain interpretations of architectural remains, capacities of past societies to adapt, and their ability to alter environmental conditions (Menotti, 2004). Lake-level records based on natural systems are better. The lake-level data presented here were obtained using a specific sedimentological method based on multiples lines of evidence, as follows:

- *Changes in the sediment structure.* Coarser deposits correspond to near-shore areas (shallower water and higher hydrodynamism).
- *Changes in the lithology.* Organic deposits (detritus gyttja, peat) often characterize shallow water or late stages of infilling (shallow residual basins). Lake marl is found in deeper water.
- *Changes in the assemblages of carbonate concretions.* The coarser fractions (>0.2 mm) of lake marl consist mainly of various carbonate concretion morphotypes of biochemical origin from bacterial (Cyanophyceae) or algal (Characeae; Haas, 1994) activity and from phenomena associated with the photosynthetic activity of aquatic vegetation. Modern analogs from ten regional lakes (Magny, 1998) highlight that each morphotype shows a specific spatial-depth distribution from the shore to the extremity of the littoral platform (Figure 2; see Overview), with the successive domination of oncolithes (near-shore areas with high-energy environment), cauliflower-like forms (littoral platform), plate-like concretions (formed on leaves of aquatic plants from the Potamogeto-Nupharetum belt), and finally tube-like concretions (stem encrustations from the Characeae belt of the platform slope). Thus, where the carbonate status of the lake allows, this sedimentological approach is similar to that based on plant macrofossils (Digerfeldt, 1988) but offers the advantage of requiring relatively small samples (~1–2 cm³).
- *Sediment hiatuses.* These mark either erosion or nondeposition. They result from a lowering of the sediment limit associated with a lowering of lake level (see Overview) for an explanation of the sediment limit). Sediment hiatuses are marked by unconformities between sediment layers (erosion surfaces; Digerfeldt, 1988), and they may be identified on the basis of observations along core transects perpendicular to the shore.
- *Contiguous high-resolution subsampling of sediment sequences identifies short-lived paleohydrological events and abrupt changes in lake level.*

Figure 1 Geographical location of the study sites.

Figure 2 Section showing the distribution of carbonate concretion morphotypes along the littoral platform of Lake Clairvaux (Jura Mountains) in relation to the morphology and the vegetation zonation. The relative frequency of each morphotype is indicated as a percentage of the sample components.

The chronology of the lake-level fluctuations reconstructed from sediment analyses is based on three methods:

- **Radiocarbon dates.** This method uses terrestrial macrofossils to avoid errors due to the hard-water effect.
- **Tree-ring dates.** The Holocene sediment sequences of many lakes in the European sub-Alpine area include anthropogenic organic layers interbedded in lacustrine deposits (Menotti, 2004). These layers consist of vegetal remains

accumulated by inhabitants of Neolithic and Bronze Age lake dwellings. Thanks to permanent humid conditions, wooden posts used by prehistoric people for house construction are well preserved in these lake-shore archaeological sites, and they provide precise tree-ring dates for lake-level changes reconstructed from sediment sequences sampled on the archaeological sites (see [Dendrochronology](#)). Thus, in the sub-Alpine area the period 6–2.8 cal ka BP is well, and precisely, documented thanks to the remains of Neolithic and Bronze Age lacustrine villages.

- *Archaeological dates.* Additional chronological control with a time resolution of ca. 50 years comes from artifacts found on archaeological sites (or related to other sites) dated by the tree-ring method, or identified with reference to already well-dated historical material (such as Roman amphoras).

The Regional Pattern of Holocene Lake-Level Fluctuations

Theoretically, lake-level records obtained from 26 sites in the same region should allow the construction of a robust regional pattern of paleohydrological changes for the Holocene. However, as more data become available, problems arise in interpreting and reconciling multiple records, most often due to uncertainties in the chronology. Sediment sequences may be poorly dated, or even when better dated, key ages may be derived by extrapolation between two radiocarbon-dated horizons assuming a regular sedimentation rate. The synthesis presented in [Figure 3](#) was constructed on the basis of more than 180 radiocarbon, tree-ring, and archaeological dates that gave the ages of the sequence of higher and lower lake-level events ([Magny, 2004b](#)).

The two histograms displayed in [Figure 3](#) show the distribution of the collected dates over the whole Holocene for the lower lake-level episodes versus the higher lake-level ones, with a time resolution of 50 years. A clear disparity appears between the two histograms: the lower lake-level episodes are better documented than the higher ones. This difference directly reflects changes in the lithology. Low lake levels often correspond to an extension of peat and organic detritus deposition in the near-shore areas, thus providing a source of datable material, whereas high stands are characterized by the accumulation of more minerogenic sediments. In addition, the archaeological sites often provide well-dated sediment sequences because of the potential for tree-ring dating. This reliance on archaeological dates may also partly explain that even the lower lake-level episodes during the first half of the Holocene appear to be more weakly documented than those of the later Holocene. This disparity also reflects the fact that early Holocene deposits often have a more offshore and deeper stratigraphic position in a lake than younger deposits. It should be borne in mind, therefore, that the patterns in both histograms are not related to the magnitude of the recorded events, but rather reflect the present state of documentation, and possibly the duration of the events (in that longer lasting events are more likely to leave an imprint).

One may observe in [Figure 3](#) that the collected dates are not distributed randomly over the Holocene, but that they cluster in successive distinct time windows. This suggests an

alternation of lake-level phases. Due to the standard deviation of the radiocarbon dates, calibration time windows of ages obtained for low and high lake levels tend to partially overlap. Moreover, except when using the ^{14}C -wiggle-matching method (see [Calibration of the \$^{14}\text{C}\$ Record](#)), radiocarbon dating does not have the precision to pinpoint the age and the duration of a short-lived event. A possible solution to overcome these difficulties was to focus on 1-sigma calibration time windows (and tree-ring dates when available). Thus, keeping in mind the limitations discussed above, 15 successive episodes of higher lake level may be identified at 11 250–11 050, 10 300–10 000, 9550–9150, 8300–8050, 7550–7250, 6350–5900, 5650–5200, 4850–4800, 4150–3800, 3500–3100, 2750–2350, 1800–1700, 1300–1100, 750–650 cal years BP, and after ca. 450 cal years BP.

Contrasting Patterns of Hydrological Changes in Europe

As pointed out previously ([Magny, 1993b](#); [Magny et al., 2002](#)), the pattern of alternative phases of lower and higher lake level observed from the data set presented in [Figure 3](#) shows a general agreement with other sequences of environmental and climatic changes established in the mid-European latitudes. The major phases of high lake level in west-central Europe coincided with glacier advance and timberline declines in the Alps and with increasing discharge in the Upper Vistula (Poland) and in the middle Durance basin (southern French Alps; [Magny, 1993b](#)). This convergence among paleoenvironmental records implies the mid-European lake-level record has climatic significance, and the records suggest continual variability over the Holocene.

A comparison of the hydrological signal given by lake levels in west-central Europe with other hydrological data obtained in Europe for the Holocene suggests that there were contrasting patterns of hydrological changes in Europe in response to known cooling phases ([Magny et al., 2003](#)). As an example, [Figure 4](#) shows the general situation in Western Europe for two distinct climatic reversals: the Preboreal oscillation (PBO) at ca. 11.2 cal years BP and the 8.2 ka event. The dry conditions to the north and south probably reflect weaker evaporation due to lower sea-surface temperatures. Furthermore, in the north a southward extension of perennial sea-ice coverage in the Nordic seas would have promoted drier conditions. The resulting stronger thermal gradient between high and low latitudes and southward displacement of the Atlantic westerly jet would have reinforced cyclonic activity over mid-Europe, leading to increasing moisture in this region.

If the maps established for the PBO and the 8.2 ka event are compared, it can be seen that during the PBO, the middle zone marked by wetter conditions appears to have been larger, extending further northward than during the 8.2 ka event. This may reflect a weaker, more meandering Atlantic Westerly Jet in response to a weaker thermal gradient between high and low latitudes. If this were the case, the climate reversal was less pronounced in Europe during the PBO than during the 8.2 ka event. A thorough understanding of the mechanisms behind these hydrological contrasts requires further investigation,

Figure 3 Distribution of the dates of higher and lower lake-level events reconstructed in the Jura Mountains, the northern French Pre-Alps and the Swiss Plateau over the Holocene period. After calibration (Stuiver et al., 1998), the dates were divided into two groups, that is, lower versus higher lake-level events, and placed on the timescale to construct two distinct histograms as follows. The temporal resolution chosen to construct the histograms was successive 50-year periods depicted as bars from 12 ka BP to present day. Every time a 50-year period was documented in a 1 or 2 sigma time window defined by the calibration of radiocarbon dates listed, it was given 2 or 1 point(s) respectively. Hence, the length of bars is proportional to the total of points accumulated by each 50-year period. Parts of the bars colored in red and green correspond with ages documented in 1 sigma calibration time windows; those in black correspond with ages documented in 2 sigma calibration time windows.

including the documentation of the role of seasonality (e.g., Hammarlund et al., 2005).

Variations in Climatic Variables Reflected by Changes in Lake Level

The quantitative reconstruction of climatic oscillations punctuating the present interglacial is one of the major challenges in paleoclimatic studies. These phenomena present a challenge to

climate modeling, and they are central to understanding the possible impact of climate change on ancient agricultural societies. Until now, most paleoclimatic data collected in Europe relate to paleotemperature, whereas reconstructions of paleoprecipitation are still uncommon. Pollen data offer the advantage of furnishing information not only on temperature but also on precipitation. However, problems arise when reconstructing past precipitation because, in Europe, the moisture of the growing season is rarely the main limiting factor for

Figure 4 Comparison of hydrological signals associated with the 8.2 ka event (a), and the PBO (b) in Western Europe. Blue broken lines: northern and southern limits of the midlatitude zone characterized by wetter climatic conditions.

vegetation on a regional scale, and modern analogs tend to span a wide range of precipitation estimates. As pointed out by Guiot et al. (1993), lake-level records can be used to refine the paleoclimatic reconstructions based only on pollen data.

This approach has been extensively described in Magny et al. (2001) (see also Approaches). The principle is to find, for each fossil pollen assemblage, several similar pollen spectra (modern analogs). The degree of similarity (or distance) is estimated between fossil assemblages and spectra from a modern reference pollen database (today including more than 1300 surface-pollen samples from Europe), among which eight to ten modern analogs are selected. The climate of these analogs is averaged to provide an estimate of the fossil assemblage climate. An additional constraint is provided by the lake-level reconstruction. Analogs giving a climate that was not compatible with the lake-level status were rejected. The climate reconstruction is therefore based only on analogs that are coherent with lake levels.

As an example, Figure 5 presents results obtained for the early and mid-Holocene periods from two sites: Lake Le Locle in the Jura Mountains and Montilier, on the south shore of

Lake Morat on the Swiss Plateau (Magny et al., 2001, 2005). Climatic parameters reconstructed here suggest that phases of higher lake level coincided with an increase in annual precipitation, a decrease in summer temperature and a shortening of the growing season. Conversely, periods of low lake level corresponded to a decrease in annual precipitation, an increase in summer temperature, and a longer growing season. This general pattern could have resulted from alternate southward-northward displacements of the Atlantic Westerly Jet and from changes in its strength in response to variations in the thermal gradient between high and low latitudes. Summer temperature estimates show fluctuations with a $\sim 2^\circ\text{C}$ amplitude, while the changes in annual precipitation reached 100/150 mm on the Swiss Plateau and ~ 200 mm at higher altitude on the Jura Mountains. However, the high variability in estimates of annual precipitation obtained at Le Locle for the Preboreal period probably reflect poor pollen analogs for that period, during which dynamic vegetation change was characterized by the reestablishment of forest cover.

Taken as a whole, these results concur with mechanisms put forward to explain changes in tree-limit altitude in the Alps during the Holocene. Observations and experiments have shown that a tree-limit decline was caused not by severe winters but chiefly by a lowering of summer temperature and a shortening of the growing season (Bortenschlager, 1977). Precipitation and summer conditions are also factors driving glacier variations in the Alps (Holzhauser et al., 2005), and variations in the production of *Najas flexilis* seeds observed in Swiss lakes (Haas et al., 1998).

As regards the possible impact of the climatic oscillations on past agricultural societies, the variations in climatic parameters reconstructed at Montilier suggest an influence of these climatic oscillations on prehistoric groups not only for the location of their villages (Figure 6), but also for their socio-economic equilibrium. Phases of cooler and wetter climatic conditions may have provoked harvest failures, more or less dramatic depending on the subsistence strategy and population density. Archaeological studies of Neolithic lake-shore villages at Lakes Chalain and Clairvaux in the Jura Mountains (5.7 and 4.5 cal ka BP) provide evidence of stronger sensitivity to bad weather conditions and increased instability when ancient agricultural communities chose to develop cereal production and a crop subsistence strategy in response to the growth of the regional population to the detriment of grazing (Arbogast et al., 1996). These observations suggest complex interactions between climatic and human factors. In agreement with the quantitative estimates of climatic variables reconstructed from pollen and lake-level data in west-central Europe, Tinner et al. (2003) have also pointed to the fact that, during climatic reversals, increasing precipitation probably had a more decisive impact than temperature decrease on former settlements in marginal elevated areas such as the Alps.

Toward a Better Understanding of the Forcing Factors

Finally, what do we know of the possible forcing factors driving the climatic oscillations reflected by Holocene changes in lake levels in west-central Europe? Several causes have been postulated, including changes in the oceanic thermohaline circulation (THC), freshwater outbursts from proglacial lakes due to

Figure 5 Climatic variables with confidence interval reconstructed from the sediment sequences of Montilier, Lake Morat (429 m, Swiss Plateau) and Le Locle (915 m, Jura Mountains). MTWA, mean temperature of the warmest month; MTCO, mean temperature of the coldest month; TANN, mean annual temperature; GDD5, growing degrees above 5 °C × days; $P-E$, precipitation minus evaporation; PANN, annual precipitation; E/PE , actual evapotranspiration/potential evapotranspiration.

Figure 6 Comparison between the atmospheric residual ^{14}C variations (Stuiver et al., 1998) and the frequency of Neolithic and Bronze Age lake-shore villages in France and in Switzerland.

Figure 7 Comparison of the Holocene record of the Polar Circulation Index (PCI) at GISP2 (Mayewski et al., 1997), the atmospheric residual ^{14}C variations (Stuiver et al., 1998), the mid-European phases of higher lake level (see Figure 3), the ice-rafting debris (IRD) events in the North Atlantic Ocean (Bond et al., 2001), and the Greenland ^{10}Be record (Bond et al., 2001).

the final steps of deglaciation in the early Holocene, and variations in solar activity (Björck et al., 1996; Bond et al., 2001; Magny, 1993a; van Geel et al., 1996).

Figure 7 shows a comparison of the mid-European lake-level record with (1) the Polar Circulation Index (PCI)

established from the GISP2 glaciochemical series (Mayewski et al., 1997); (2) the atmospheric ^{14}C residual series (Stuiver et al., 1998); and (3) the North Atlantic ice-rafting debris (IRD) record (Bond et al., 2001). The PCI is thought to provide a relative measure of the average size and intensity of polar

Figure 8 Comparison of early Holocene cooling phases in west-central Europe as reflected by highstands of lake levels (see Figure 3) with the atmospheric ^{14}C residual record (Stuiver et al., 1998), the Greenland ^{10}Be record (Bond et al., 2001), and freshwater outbursts from north-European and North American proglacial lakes (Jansson and Kleman, 2004; Teller et al., 2002).

atmospheric circulation. The radiocarbon curve may be considered as a proxy record of past changes in solar activity while IRD peaks indicate cooling events punctuating the whole Holocene in response to variations in the solar irradiance. In general, as pointed out by Magny (1999), phases of higher lake level in west-central Europe coincided with IRD events, and ^{14}C and PCI maxima. This supports the hypothesis that changes in solar activity were a major driving factor of Holocene climatic oscillations.

As illustrated by Figure 6, another indirect indication of a possible link between solar activity and mid-European lake-level fluctuations may be observed for the period 6–2.8 cal ka BP, when there are close correlations between the atmospheric ^{14}C residual record and the frequency of the Neolithic and Bronze Age lake dwellings well dated by dendrochronology.

Finally, Figure 8 compares the phases of higher lake level in west-central Europe with the atmospheric ^{14}C and Greenland ^{10}Be records, which here are proxies for past fluctuations of solar activity, and freshwater outbursts from different proglacial lakes that punctuated the deglaciation in Europe and North America. These meltwater flooding events could have induced decreases in THC (Björck et al., 1996; Jansson and Kleman, 2004; Teller et al., 2002).

Two kinds of situations may be distinguished from data illustrated in Figure 8. First, meltwater pulses at 11300–11250–11200–11170, 10400–10300–10200, 9500, 9200, 8400, and 7500–7000 cal years BP happened at times characterized by minima in solar activity or immediately preceded them. They led to widespread cooling events in the North Atlantic area and are marked by high lake levels in west-central Europe. Second, the freshwater outbursts at 10600–10000, 8000–7500, and 7000–6400 cal years BP resulted neither in a widespread cooling event nor in a rise in mid-European lake levels. This second type of meltwater event occurred during periods of solar activity maxima.

These contrasting patterns suggest that solar activity may have played a crucial role in amplifying or damping the possible effects of meltwater flooding events on the climate (Magny and Bégeot, 2004).

Introduction

Lakes have been recognized as paleoclimatic indicators for a long time. Lakes respond to changes in the local water balance by changing in depth and area. Lake water balance is in equilibrium with climate changes and therefore can be used as an indicator of past climate. Changes in the lake water balance affect a variety of biological, limnological, and sedimentological processes within the lake and changes in these processes are often recorded in the lake sediments. Therefore, investigations of lake sediments can be used to reconstruct past lake-level changes and hence the past climate changes.

Closed-basin lakes are most sensitive to climate changes; these are widespread today in arid and semiarid climate areas (Street-Perrott and Harrison, 1985). Lake sediments and the position of the past shorelines indicate that lake water levels in those areas were much higher (in the magnitude of 10–100 m) in the past. The water balance of open-basin lakes has been relatively less studied, because of the assumption that they are insensitive to climate changes and should respond to changes in water balance through changes in discharge rather than in lake level. However, Digerfeldt (1986) developed a method for reconstruction of past lake-level changes using detailed biostratigraphic investigations. He found that lakes in southern Sweden had experienced significant lake-level lowering (in magnitude of up to 10 m) during the Holocene. Many other investigators used Digerfeldt's approach and found that significant lake-level changes in open-basin lakes in humid climates have occurred in the past. So the geological records of both closed-basin and overflowing lakes have been used successfully to reconstruct lake-level changes during Quaternary. However, the geological record indicates whether the climate was generally wetter or drier, but tells us little about the specific nature of the climate changes involved. Empirically, it was understood how water-level fluctuations in arid and semiarid areas were driven by climate changes, but the low lake levels in humid climates were difficult to explain only by climate changes. A possible approach to understanding the interaction between climate change and lake-level fluctuations is through modeling.

The Basis of Lake-Level Modeling

Lake models can be described as either deterministic or stochastic (Henderson-Sellers, 1984). Deterministic models assume that variables can be well specified and simulated, while stochastic models allow for some random variation in these variables. Deterministic models are common but stochastic ones are very rare. Further, models can be either conceptual or empirical. Conceptual models are based on physical reasoning while empirical models are largely statistical fits to

observational data. Deterministic–empirical relationships were commonly used in the earliest attempts to understand past lake-level fluctuations. A direct statistical correlation was assumed between evaporation (or lake level) and some meteorological variable, such as air or water temperature. However, empirical estimates of evaporation oversimplified the interaction between a lake and the overlying atmosphere. Both evaporation and lake water temperature are actually determined by the lake energy balance (Henderson-Sellers, 1984). Lakes with different morphometries and physical characteristics have different thermal and water balance regimes, and empirical relationships are usually valid only for the specific lake for which the relationship was developed. Therefore, empirical relationships are not ideal for predicting the likely impact of climate changes (either past or future) on other lakes with different morphometries and in different climates.

Models for paleoclimate studies should necessarily be conceptual or physically based (i.e., based on the underlying physics or chemistry of the phenomena being described), in order to eliminate questions regarding the applicability of the model in the past (or similarly, in the future) when statistical relationships among variables may have significantly differed from those at present. Conceptual lake models, which explicitly represent the physical processes governing the energy and water balances of the lake, offer a more robust way to predict climate-induced changes in lake water volume, level, and discharge. Such models allow an assessment of the relative importance of individual climate controls and the interactions among them and testing of specific paleoclimatic hypotheses.

Lake Water Balance

The response of lake volume, and hence level, to climate changes is given by the lake water balance equation (Mason et al., 1994; Street-Perrott and Harrison, 1985):

$$\frac{\Delta V}{\Delta t} = (R + P + G_1) - (D + E + G_0)$$

where the change in lake volume (ΔV) with time (t) is the difference between water inputs and outputs. Water inputs to the lake are runoff (R) from the catchment, precipitation (P) over the lake surface, and groundwater influx (G_1). Water outputs from the lake are outflow or discharge (D), evaporation (E), and groundwater discharge (G_0) (Figure 1). Most paleomodeling studies assume that groundwater fluxes are negligible ($G_1 - G_0 \approx 0$), and changes in lake volume (and level) can be derived from the water fluxes over the lake and catchment, providing that it is possible to calculate amount of discharge – although models do exist that take groundwater fluxes into account (Cardille et al., 2004). When groundwater fluxes are negligible, evaporation, runoff, and discharge need to be

Figure 1 Main components of the lake water balance.

calculated. Lake physical models derive evaporation from the lake energy balance and runoff from the soil moisture balance.

Lake Energy Balance

Evaporation is one of the important factors controlling the lake water volume and level, especially in closed-basin lakes. Evaporation occurs when a vapor pressure deficit between a lake surface and the overlying atmosphere exists and sufficient energy is available. Evaporation is affected by meteorological factors, such as solar radiation, air and water temperatures, wind speed, and humidity, but also by physical characteristics of the lake such as the size of the lake surface area and water quality. Many formulas exist to calculate evaporation, and they require lake water energy-balance modeling (e.g., [Burman and Pochop, 1994](#); [Henderson-Sellers, 1984](#)).

Lake Surface Energy Balance

The lake water temperature can be derived from the lake water surface energy balance (SEB), where the SEB is the sum of all energy fluxes across the air–water interface of a lake ([Figure 2](#)). However, a significant amount of heat is stored in the lake water during the heating period (e.g., this is summer in the Northern Hemisphere extratropics) and is released during the cooling period (autumn in the Northern Hemisphere extratropics). This thermal inertia causes lake heating to be out of phase with solar radiation and air temperature forcing ([Hostetler and Bartlein, 1990](#)). Therefore, to calculate lake water temperature and evaporation, some stratification (vertical heat transfer) is required in the model.

Two types of stratification models have been used: eddy-diffusion (or differential) and mixed-layer (or integral) models ([Henderson-Sellers, 1984](#)). Comparison between these two types of models suggests that they are complementary rather than competitive. Mixed-layer models have been widely used in lake studies, although they have some limitations because of instability when run for long periods ([Henderson-Sellers and Davies, 1989](#)). Eddy-diffusion models are numerically more stable over long integrations and have been successfully used

Figure 2 Main components of the lake energy balance model. SW is shortwave radiation and LW longwave radiation, both of which are partly reflected and/or absorbed by the lake water surface.

in a variety of lake studies (e.g., [Hostetler and Benson, 1990](#); [Vassiljev, 1998](#); [Vavrus et al., 1996](#)).

Lake Ice Models

During cold periods, lakes in the mid- and high latitudes will ice over; this increases the surface albedo (reflectivity) and limits the amount of solar radiation penetrating into the water of the lake. This ice cover will significantly alter the lake energy balance (and hence evaporation). Therefore, the models used for lakes in cold climates incorporate some type of thermodynamic ice model to simulate the accretion and ablation of ice and the snow covering the ice ([Hostetler, 1991](#); [Patterson and Hamblin, 1988](#); [Vassiljev et al., 1994](#); [Vavrus et al., 1996](#)).

Soil Moisture Balance

Runoff from the catchment is an important source of water inputs to lakes, especially in humid climates. Changes in runoff are related to climatic factors, such as precipitation and actual evapotranspiration, but they are also affected by some catchment-specific characteristics, such as soil texture and vegetation cover ([Figure 3](#)). Soil texture determines the water-holding capacity of the soil, which in turn determines the extent to which moisture is carried through into drier seasons. When the soil moisture storage is large, there can be a significant time lag between precipitation events and runoff. The density of the vegetation and the type of vegetation (e.g., grasses or trees) affects the rate of actual evapotranspiration and hence the amount of water that can be removed from the soil.

The physically based models currently used to predict runoff are basically soil moisture balance models ([Evans and Trevisan, 1995](#); [Harrison et al., 1993](#); [Haxeltine et al., 1996](#);

Figure 3 Simplified principles of the soil moisture balance models. Soil receives moisture from precipitation (in the form of rain or snow) and releases it through actual evapotranspiration (determined by vegetation type and by soil water and energy supply) and runoff. Precipitation infiltrates into the soil at a rate determined by soil texture. Moisture in the soil percolates at a rate determined by soil texture and moisture content, and when the soil moisture is at field capacity runoff occurs.

Prentice et al., 1992). The models have been developed from the so-called Budyko 'bucket' model, as reformulated by Manabe (1969), in which the soil was considered as a single simple water store of fixed depth. Although some soil moisture models preserve this concept (Evans and Trevisan, 1995; Harrison et al., 1993; Prentice et al., 1992), there are more complex models wherein the soil is subdivided into two (Haxeltine et al., 1996) or even more (Nikolaidis et al., 1993) compartments. The incorporation of multiple soil layers allows a more explicit differentiation between the rate of initial infiltration into the soil and the rate of transmission of water through the soil column. More importantly, it permits differences in the rooting depths of different plant types (and hence in their ability to compete for water) to be taken into account explicitly. Although all physically based soil moisture models include a vegetation, the treatment of the vegetation varies in complexity. While the simplest models implicitly consider only the presence/absence of vegetation, more complex models allow for a number of different vegetation types, which differ in factors such as albedo, phenology, and rooting depth.

Discharge

Lakes in humid climates usually have a surface outlet in the form of a stream or river. The form of this outlet can be changed by erosion and infilling, except in the case where the outlet is cut through solid bedrock (Dearing and Foster, 1986). It is difficult to determine the size and the shape of the outlet at specific times in the past. However, since it is necessary to allow for possible changes in outflow volume, then some approximation of past outflow parameters must be made. It is usually assumed that the shape of the channel outlet and basin have not changed substantially through time. The simplest way to

calculate the volume of outflowing water is as a function of the outlet cross-sectional area and the velocity of the flow. The flow velocity at the outlet can be calculated using, among the others, the Manning equation (Bras, 1990). In this way, only the cross-sectional area of the outlet and the slope of the outflow channel need to be specified. These parameters can be obtained, for example, from detailed contour maps.

Input Data

The models are usually driven by monthly meteorological data including solar radiation, air temperature, vapor pressure, cloudiness, wind speed, and precipitation. Some basin-specific parameters, such as lake bathymetry, are also required. Most of the models run with a daily time step.

Modeling Strategies

Modeling consists of three main aspects: model development, which has been described above, validation, and application phase. Models must be validated under modern climate conditions, preferably using long instrumental records of climate and hydrology (Hostetler and Benson, 1990; Vassiljev, 1998). The validation shows how correctly the model simulates the observed behavior of the lake (e.g., water level) and indicates the weaknesses of the model that need to be improved. One of the most extensively validated models, developed by Hostetler and Bartlein (1990), was successfully validated with observed evaporation and surface temperature data from three North American lakes: Salton Sea (years 1961–62, California), Pretty Lake (years 1963–64, Indiana), and Pyramid Lake (years 1987–88, Nevada). Later the modified model (Vassiljev et al., 1994, 1998) was successfully validated against observed lake-level data for lakes in northern Europe: Lakes Viljandi (years 1940–90) and Karujärv (years 1976–87, Estonia), and Lake Bysjön (years 1973–77, southern Sweden).

In the application phase, two modeling strategies are used to examine the response of a lake to a change in climate forcing: simulation and sensitivity analyses.

Simulation Analysis

In simulation mode, known changes in climate forcings at a given time are used to drive the model. A number of climate parameters, such as solar radiation, temperature, precipitation, vapor pressure, cloudiness, and wind speed, are required. Many types of paleoenvironmental data can be used to reconstruct the required climate parameters for model input. For example, there are well-known changes in solar radiation (insolation) during the Holocene (Berger and Loutre, 1991) and pollen-based reconstructions of temperature and precipitation. Unfortunately, not all parameters can be reconstructed from proxy data directly. For example, there are limited possibilities to reconstruct changes in wind speed and cloudiness from proxy data (although see Adams and Tetzlaff, 1984; Harrison et al., 1993). Models use the present-day mean or extreme values for such parameters. Other possible climate data sources used in the modeling are general circulation

models (GCMs), which can provide all required data (e.g., Hostetler and Benson, 1990).

Sensitivity Analysis

In sensitivity mode, the climate forcing is changed systematically, possibly but not necessarily within a range determined by actual, observed changes. This allows the testing of the importance of every climate parameter, individually or in some combination, for the lake water balance.

Modeling Results

The Effect of Changes in Solar Radiation

Variations in the Earth's orbital parameters (precession, tilt, and eccentricity) are known to have caused significant changes to the seasonal and latitudinal distribution of incoming solar radiation (insolation) during the Holocene (Berger and Loutre, 1991). For example at 9 ¹⁴C ka BP, when perihelion was in June rather than in January as in the present, summer insolation in the Northern Hemisphere was ~6–16% greater than today (depending on latitude), but winter insolation was reduced by 7–16% (Table 1). Earth's orbital speed is greatest near perihelion and least at aphelion. The shift from perihelion in June at 9 ¹⁴C ka BP to perihelion in Jan today has resulted in changes in the lengths of the climatological winter and summer seasons (Kutzbach and Gallimore, 1988): the Northern Hemisphere summer was shorter by ~6 days, and winter accordingly longer (Table 2). These orbitally induced anomalies gradually attenuated through the Holocene. In most lake models, solar radiation is modified according to orbital changes and formulas suggested by Berger and Loutre (1991). In some models (e.g., Harrison et al., 1993; Vassiljev et al., 1998), the lengths of each

month under different orbital configurations are also modified using a procedure proposed by Kutzbach and Gallimore (1988), in which the beginning and end of each celestial month is defined by celestial longitude.

Modeling studies show that orbitally induced changes in solar radiation and in the lengths of the climatological seasons affect the lake water balance in both open- and closed-basin lakes. However, the changes are small and cannot explain either the magnitude or pattern of observed lake-level changes during the Holocene.

Simulation Analyses

The earliest paleomodeling studies were mainly concentrated on closed-basin lakes in arid and semiarid climates. Only from the 1990s have open-basin paleolakes in humid climates been modeled. These studies showed the changes in climate that were required to produce the observed patterns of lake-level change.

Paleolake Chad

One of the first water balance modeling studies was for Paleolake Chad (northern Africa), where the magnitude of climate changes required to explain lake fluctuations was estimated. A combined hydrological and energy-balance model was first applied to Paleolake Chad by Kutzbach (1980) to estimate climate conditions between 10 and 5 ka BP, when the water level of the lake was 40 m higher than present. Kutzbach found that such a high water level could exist only when the annual precipitation was at least 600–650 mm (double that of the present). However, these precipitation values are minimum estimates, because Paleolake Chad had risen to the overflow level and the volume of discharge was unknown. Later Adams and Tetzlaff (1984) simulated climate conditions for the Last Glacial Maximum (18 ka BP). Their simulations suggested that south of the lake air temperature was 4 °C lower than in present times, while the north of the lake was 6 °C lower. Lower temperatures were paralleled by decreases in annual humidity, and annual precipitation was 75 mm (five times lower than present). Lower humidity reduced cloud cover by 10% and increased solar radiation by 10%. These climate parameters were used to drive the model; results showed that the northern part of Paleolake Chad would have dried up and only a very shallow lake with water temperatures around 40 °C would have existed in the southern part. This too probably disappeared in some years.

Table 1 Example of insolation values at the top of the atmosphere during the Holocene at 55° N according to orbital parameters given by Berger and Loutre (1991)

Time (¹⁴ C years BP)	Perihelion (°)	Tilt (°)	Eccentricity	Insolation (W m ⁻²)	
				July	January
0	282.04	23.446	0.016724	457	64
3000	231.08	23.820	0.017824	468	61
6000	164.28	24.167	0.018911	491	57
9000	114.82	24.227	0.019419	500	56

Table 2 Changes in month length during the Holocene as a result of changes in the timing of perihelion

Time (¹⁴ C years BP)	Length of month (number of days)											
	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
0	31	28	31	30	31	30	31	31	30	31	30	31
3000	32	30	31	31	31	30	30	30	29	30	30	31

9000	33	31	31	30	30	28	29	29	29	31	31	33

Paleolake Lahontan

High lake-level stands in Paleolake Lahontan (USA, Nevada) between about 13.5 and 11 ^{14}C ka BP were modeled using an energy flux balance model (Benson, 1981). High stands of Lake Lahontan were achieved by increasing historical values of cloudiness by 10% and by reducing the mean air temperature by at least 10 $^{\circ}\text{C}$, so that evaporation rates were an order of magnitude lower than present times. This was sufficient to support water levels 150 m higher. Hostetler and Benson (1990) conducted experiments based on the simulations of atmospheric GCMs, which indicate that during the late Pleistocene, the polar jet stream was split around the North American ice sheet. The position of the southern branch of the jet stream around 18 ^{14}C ka BP was $\sim 33^{\circ}\text{N}$ during winter and $\sim 45^{\circ}\text{N}$ during summer (currently 42°N during winter and 58°N in summer). They found that such a change in the position of the polar jet stream brought precipitation further south than at present and led to enhanced wetness in the area of Paleolake Lahontan ca. 20–13.5 ^{14}C ka BP. After 13.5 ^{14}C ka BP the jet stream shifted northward and aridity increased. The enhanced effective moisture was thus a result of increased precipitation combined with a reduction in evaporation due to increased summer cloudiness. Evaporation was estimated at 42% lower than today and the required precipitation was 540 mm, 1.8 times higher than historical maximum. The lake-level drop of 135 m from the maximum stand to Holocene levels could have occurred within 300 years. Later Hostetler (1991) showed that ice cover could have existed up to 4–4.5 months on the lake, leading to significant decreases in annual evaporation (about 60% from present value). Under these conditions, the precipitation requirement to maintain the high stand of the lake was similar to the historical maximum value (300 mm) from the year 1983.

Lake Bysjön

Biostratigraphical studies showed that Lake Bysjön (southern Sweden) experienced several episodes of major lake-level lowering during the Holocene, with the maximum around 9 ^{14}C ka BP, when water level dropped by 7 m (Figure 4). Modeling was used to investigate if it was possible to reproduce the observed lake-level changes through the Holocene by combining the precipitation changes with known changes in radiation and pollen-based temperature reconstructions (Vassiljev et al., 1998). Temperature reconstructions showed that the mean annual temperature was higher than today (up to 2 $^{\circ}\text{C}$) during the Holocene, caused mainly by increased winter temperatures, except in the period around 7 ^{14}C ka BP when winters were about 1.2 $^{\circ}\text{C}$ colder than today. Summers were slightly cooler (0.6–1.6 $^{\circ}\text{C}$) most of the time, except around 7 ^{14}C ka BP, when they were warmer by about 1.8 $^{\circ}\text{C}$.

Modeling showed that to produce a 7-m water level drop at 9 ^{14}C ka BP, changes in radiation and temperature (January warmer 2.3 $^{\circ}\text{C}$, July cooler 0.6 $^{\circ}\text{C}$ than today) must be accompanied by a decrease in annual precipitation of 75 mm (13% less than the present value of 587 mm; Figure 4). When winter temperatures were warmer than today, a reduction of runoff into the lake occurred. Together with relatively small changes

Figure 4 Simulated lake-level changes for Lake Bysjön (southern Sweden) during the Holocene in response to changes in radiation and pollen-based temperatures, together with different annual precipitation values (modern precipitation 587 mm and annual precipitation reduced by 25, 50, 75, and 200 mm). Blue line shows the water-level fluctuations reconstructed by biostratigraphical studies, 0 m corresponds to the present-day lake level.

in precipitation, this caused the lake to become closed, and the water level dropped significantly.

The simulations also indicated that an observed high water level around 7 ^{14}C ka BP, when the winter was colder and summer warmer than today, could have occurred even when there was a significant reduction in annual precipitation. For example, decreases in annual precipitation of 200 mm could cause only 0.4 m drop in the lake level (Figure 4). This apparent contradiction relates to winter temperatures colder than present, which significantly reduced the actual evapotranspiration. Decreases in runoff from spring snowmelt were relatively small, and the total volume of the runoff was sufficient to maintain the high water level. Experiments showed that all the observed lowerings occurred when winter temperatures were warmer than today. Thus, even though changes in precipitation appear to be the driver of observed lake-level changes, the trigger seems to be changes in winter temperature. This study demonstrated that lake levels in humid temperate climates are sensitive to changes in winter climates rather than changes in summer climates.

Sensitivity Analyses

As the examples above illustrate, changes in lake water balance can be caused by a range of different climate variables. Harrison et al. (1993) used a simple water balance model to change a number of climate parameters in accordance with paleo-observations. They showed that known changes in solar radiation, temperature, and cloudiness were unable to produce observed changes in lake level in Europe during the Holocene. Prentice et al. (1992) and Evans and Trevisan (1995) found that changes in the seasonality of precipitation could explain observed changes in lake levels in southern

Europe. [Prentice et al. \(1992\)](#) showed that a shift in precipitation to the winter period without changes in the total annual precipitation, was sufficient to maintain high lake levels at Lake Ioannina (northern Greece) at the Last Glacial Maximum. Moreover, they found that a shift in precipitation seasonality, combined with colder temperatures, could explain the coexistence of high lake levels and steppe vegetation in the eastern Mediterranean. [Evans and Trevisan \(1995\)](#) obtained similar results at the Lagoni peat-bog (northern Italy), showing that mesic conditions indicated by pollen data and humidity conditions suggested by lake level are not in conflict, but could be caused only by changes in the rainfall seasonality.

[Vassiljev \(1998\)](#) investigated the sensitivity of lakes to changes in precipitation. Systematic changes in annual and seasonal precipitation were applied to three lakes from northern Europe (Lake Bysjön, southern Sweden, and Lakes Karujärv and Viljandi in Estonia; [Figure 5](#)). Simulations showed that lake level is more sensitive to decreases than increases in precipitation. In cold/temperate humid climates, actual evapotranspiration is close to potential evapotranspiration, and increased precipitation leads to increased runoff. However, increased runoff is compensated for by increased discharge

and lake-level change is small. Reduction in winter precipitation had a much bigger impact on the lake levels than changes in summer precipitation. In cold/temperate humid climates an important component of runoff is snowmelt, and therefore to produce significant changes in runoff, unless there are changes in the winter climate are required.

Effect of Lake Morphometry

Since lakes vary in their morphology, sedimentation, and water balance type ([Street-Perrott and Harrison, 1985](#)), it is plausible that different responses of lakes to the same change in climate could reflect basin parameters. Some studies ([Dearing and Foster, 1986](#); [Magny, 1992](#); [Vassiljev, 1998](#)) suggested that lake level is sensitive to the ratio of the lake area to the catchment area. The behavior of 156 overflowing artificial lakes (in northern Europe) was examined to evaluate the influence of lake area and catchment area on responses to precipitation changes under modern climate conditions ([Harrison et al., 2002](#)). The results show that lake response to prescribed precipitation changes is determined by the ratio of the lake area to the catchment area. However, the limiting value of the ratio varies according to the magnitude of the prescribed change. For example, a decrease in mean annual precipitation of 200 mm (or 34%) produces a significant decrease in lake level when the catchment area is less than ten times larger than the lake area. A decrease in precipitation of 100 mm (or 17%) can produce a significant decrease in lake level only when the catchment area is less than two times larger than the lake area. [Cardille et al. \(2004\)](#) showed that groundwater-dominated lakes in North America behave in a similar way.

The results of these experiments help to explain earlier empirical studies that classified the response of lakes to climate change by lake water balance type. [Street-Perrott and Harrison \(1985\)](#) identified three kinds of lakes: atmosphere-controlled lakes (precipitation–evaporation), amplifier lakes (runoff–evaporation), and reservoir lakes (runoff–discharge). The main source of water input for atmosphere-controlled lakes is precipitation and for amplifier lakes it is runoff; both types of lakes lose water through evaporation. The main water input for reservoir lakes is runoff and water is removed mainly by discharge. They found that reservoir lakes are of little use as paleoclimatic indicators and closed-basin amplifier lakes are the most sensitive to climate changes. The results of [Harrison et al. \(2002\)](#) and [Cardille et al. \(2004\)](#) indicate that lake water balance type is related to the ratio of lake area to catchment area. Lakes with relatively large catchments tend to be reservoir lakes, and lakes with relatively small ones tend to be atmosphere-controlled lakes. The modeling results suggest that water level of the open-basin lakes with relatively small catchments, where runoff is less important, is sensitive to climate change, because their outlets close easily. Only amplifier and atmosphere-controlled lakes can be closed-basin lakes (water output is only through evaporation), because their water level is most sensitive to climate change. However, reservoir lakes can also be used for climate change studies but only if some other water quality parameters that are not dependent on the water level are used.

Figure 5 Simulated changes in lake level at Lake Bysjön (a), Lake Karujärv (b), and Lake Viljandi (c) in response to changes in annual winter or summer precipitation. The changes are expressed as anomalies from the present; dashed lines mark the level at which the lake is dry.

Conclusions

Lake-level modeling studies have successfully simulated the balance of closed- and open-basin lakes. The models have helped to explain the climatic factors behind lake-level fluctuations. Lake level of closed-basin lakes in arid climates is more sensitive to climate variables that control evaporation from the lake, such as temperature and cloudiness. The water level of open-basin lakes in humid climates is related to runoff, which is controlled by precipitation. Lake-level fluctuations can be simulated using realistic ranges of climate variability, often with more than one climate variable changing at the same time.

Simulations also explain why not all lakes respond to climate change in the same way: the sensitivity of lake level to climate change is determined by lake morphometry, especially by the ratio between lake and catchment.

Origins of Lichenometry

Lichenologist Roland Beschel is widely recognized as being the first to show how lichens could be used to estimate the timing of glacier retreat and other geomorphic activity (e.g., Webber and Andrews, 1973). While doing lichenological research in cemeteries, Beschel noticed that larger lichens were found on older gravestones. It was clear to him that individuals of certain lichen species were slow-growing and long-lived and grew radially outward to form crust-like, almost circular patches on the rocks. When he saw many of these same crustose lichen species growing downvalley from retreating glaciers, Beschel reasoned that the diameter of these lichens could be used as a relative measure of the amount of time that glacial debris had been exposed, stable, and available for lichen colonization and growth. Though Beschel died before he could fully explore the potential of his lichen dating technique, his early work (e.g., Beschel, 1950, 1961) has sparked considerable interest among scientists who work in lichen-rich polar and alpine areas. Following Beschel's lead, hundreds of earth scientists have used lichenometry to estimate the timing of geomorphic events on such features as raised beaches, debris flow and rockfall deposits, and morainic ridges, as well as to estimate the age of archaeological features. Potential users of lichenometry typically learn about the technique by studying the detailed reviews that trace the historical development of lichenometry and describe a variety of sampling designs that users can adapt to fit their particular application and field circumstances (e.g., Innes, 1985, 1988; Locke et al., 1979; Matthews, 1994; McCarthy, 2002; Noller and Locke, 2000; Webber and Andrews, 1973).

Lichenometry is now a widely accepted and much used dating technique that continues to evolve. Prior to the 1980s, thallus measurement was often done with rulers, and the location and size of a few of the largest thalli were reported. Since the 1980s, lichenometry has evolved from being a descriptive report of thallus sizes and tentative age estimates to reports that assign ages and error bars using approaches that increasingly rely on trend fitting software, polynomial equations, and assumptions that defy articulation. Initially, the shift toward statistical manipulation was seen in paleoseismic applications (e.g., Bull and Brandon, 1998; Smirnova and Nikonov, 1990). Now, few studies use the sort of descriptive lichenometry that was commonplace in the 1980s. Bradwell (2010) has rightly noted that this statistical shift has led to less transparency in the way lichenometry is practiced. It should also be noted that today there is no scientific debate, and little research focused on the fundamental assumptions of lichenometry. This is evidenced by the small number of papers that have offered constructive criticism of lichenometry (e.g., Jochimsen, 1966; Kirkbride and Dugmore, 2001; McCarthy, 1999; Schuhwerk, 1992).

The following sections provide a general overview of lichenometry with a special focus on the rationale, assumptions, and especially the strengths and limitations of the more

common approaches to lichenometry. The article concludes with some practical suggestions and a brief critique of lichenometry. Potential users are advised to consult specific references for more detailed information about sampling designs and data analysis.

Rationale and Assumptions

Lichenometry is based on several key assumptions.

- (a) A surface can be no younger than the oldest individual lichen (thallus) growing on it. Thus, while the age of an individual lichen is usually unknown, the lichenometric age is a minimum estimate of surface age.
- (b) Thalli with circular or nearly circular outlines are individuals that grew radially outward from a central point. Thalli that do not have a circular outline are not suitable for lichenometry because they may have developed by coalescence of neighboring lichens.
- (c) The radial growth of lichens is sporadic, but is assumed to be constant when averaged over the long term.
- (d) The largest lichen is not necessarily the oldest, but it is among the first to have become established after all others were stripped from the surface by the last major disturbance (e.g., glacial activity).
- (e) The largest lichen occupies an optimal site for growth and is the fastest growing in the community.
- (f) The diameter of the largest or several of the largest lichen thalli with oval or circular thallus outlines can be used to estimate the time elapsed since colonization began.

These basic assumptions were broadly outlined in Beschel's early publications. Some are not used in certain approaches to lichenometry and some have been challenged by critics as being biologically untenable (e.g., McCarthy, 1999). The assumptions are seldom stated and are occasionally modified by users so as to permit the use of certain statistical tests. Additional assumptions about errors in search, thallus measurement, or species identification are also implicit. These potential sources of error are of significant concern especially if field work is done by a team of people and/or involves *Rhizocarpon geographicum* (L.) DC. and some of its look-alikes that may not grow at similar rates. While users may be reassured if a lichenologist identifies voucher samples of the general types of lichens that were measured in the field, it is difficult to evaluate the thoroughness of the field search, the representativeness of the voucher samples, the accuracy and precision of the measurements, or the closeness of the age determinations. As few, if any, studies use quantitative testing to assess the impact of the potential sources of error on their age estimates, there is little reason to place trust in the reproducibility and accuracy of lichenometric ages. At best, lichenometric ages are minimum estimates of surface age.

Approaches to Lichenometry

Unlike many other dating techniques, lichenometry does not use a single standardized approach. Consequently, almost anyone – regardless of their understanding of lichen biology – can generate and manipulate lichen size data sets so as to produce statistically reproducible age estimates. Unfortunately, statistical reproducibility (e.g., Matthews, 1974, 1975) does not guarantee accuracy or precision, and the many potential errors associated with data collection, interpretation, and growth rate calibration cast doubt as to how closely some lichenometric ages match the true age of the surface (e.g., Kirkbride and Dugmore, 2001). Given such concerns, it is wise to clearly report ages generated by lichenometry as ‘lichenometric ages’ and place more trust in age estimates that are supported by independent dating techniques.

Each new user of lichenometry seems to adopt a slightly different approach to sampling and data interpretation, but most studies use a variant of two or three ‘schools’ of lichenometry. The following sections outline these basic ‘schools’ or approaches.

Relative Dating Using Lichens

Lichens can be used to provide either a relative or a calendric (semiabsolute) age for a surface. For example, where lichen cover has been disturbed by a flood or other geomorphic event so that there is a sharp demarcation between lichen-free and lichen-rich areas (i.e., a lichen trimline), then younger and older surfaces can be readily identified (Figure 1). Assigning relative ages in such settings does not require knowledge of lichen growth rate and assumes that the dominant geomorphic process(es), not microclimate or other factors, are solely responsible for obvious differences in lichen cover. This sort of relative age dating with lichens is easily done and is widely accepted, but it is best restricted to situations where there are clear lichen trimlines (e.g., Timoney and Marsh, 2004). If relative age dating is to be attempted where there are only

slight differences in lichen cover, it is both necessary to accurately measure lichen cover in a systematic way and to find clear evidence that changes in percentage cover are due to specific geomorphic events. In general, percentage lichen cover and relative age dating using lichens have a greater chance of success on silicate rocks where lichen populations can be quite large and uniformly distributed. However, these are not well suited for use on carbonates where lichens are sparsely distributed, and colonization and growth rates can be strongly influenced by chemical weathering, microtopography, and nitrogen enrichment at bird perches and rodent burrows (McCarthy and Smith, 1995). The use of percentage lichen cover as an index of age usually involves subjective judgment about where to sample and how to accurately measure cover (e.g., Innes, 1986; McCarthy and Zaniewski, 2001). As lichen cover can vary due to imperceptible differences in microclimate, geochemical differences in substrates, and many factors other than geomorphic disturbance or surface age, the use of percentage cover as a dating tool is not widely trusted or used (e.g., Noller and Locke, 2000, p. 266). Nevertheless, relative age determinations can sometimes be accurately estimated if the successional indicator status of certain lichen species can be established (e.g., Hill, 1994; Schuhwerk, 1992).

Lichen Growth Rate Calibration

A calendar year can be estimated for the stabilization of a moraine or other lichenized substrate if a quantitative link can be made between some measure of lichens at the site and the age of the lichenized substrate. This relationship is often represented by a scatterplot that has traditionally been called a ‘lichen growth curve.’ This is an unfortunate misnomer. The line plotted through the points is not always a curve, and indices of lichen size (e.g., a radius of an imperfect circle) are plotted against surface age. The change depicted by such a plot is a change in the relationship between the substrate age and the lichen size index. This is not equivalent to a lichen

Figure 1 A lichen trimline was formed on these quartzite boulders when the lichen-covered moraine was eroded by a stream. Historical photographs and tree ring dating show that lichen cover on this moraine originated in the late 1890s when the Illecillewaet Glacier retreated from this position. Since *Rhizocarpon geographicum* agg. takes ca. 15 years to become established on recently exposed rocks in the region, the lichen-free area in the abandoned stream channel is less than ca. 15 years old.

growth rate. True lichen growth 'curves' use repeated measurements (e.g., at exactly the same lobe) of the exact same thallus (thalli) over a certain period of time. Workers who rely on indices of thallus or population size (e.g., largest inscribed diameter or largest five or ten thalli at a site) have not tracked historical changes in marked thalli and have a tenuous basis on which to define lichen growth rates or infer biological process from the shape of thallus size distributions. However, it is commonplace in lichenometric dating to report that the lichenometric 'growth curve' is an estimate of the long-term radial growth rate of lichens that has been 'calibrated' at that site. The radial growth trend of crustose lichens is typically represented by a scatterplot that pairs the diameter or some other measure of lichen size (e.g., longest axis, shortest axis, or diameter of the largest inscribed circle) with the approximate age of the substrate surface. As ages estimated by lichenometry are an approximation of the amount of time elapsed since lichens first colonized the surface, the true age of the surface may be older.

Lichenologists have long used repeated measurement of marked thalli to estimate lichen growth rates and document short-term changes in lichen communities (e.g., Smith, 1995). Direct measurement of lichen growth can be done using calipers, pen and ink tracings on acetate overlays, photogrammetry and/or digital photographs, and Geographic Information Systems (e.g., Benedict, 1990, 2008; Brabyn et al., 2005; Hooker and Brown, 1977; Proctor, 1983). In each case, changes in lichen size are measured relative to painted markers or rock crystals. As the radial growth of epilithic lichens is often slow (e.g., $<0.5 \text{ mm year}^{-1}$) and uneven, direct measurement must be done using repeated measurements to acceptable tolerances (e.g., $\pm 0.01 \text{ mm}$), and they should ideally be done along several radii at many thalli. The slight swelling that occurs when thalli are wet and the distortion associated with photographic lenses, parallax error, and problems in exactly repositioning a camera for repeat photography are important potential sources of error that can be quantitatively assessed and minimized. However, this is tedious and exacting work and few workers use this approach for the purpose of assigning lichenometric ages. Even when detailed records of radial growth are compiled, very few workers have attempted to compare annual growth rate measurements to indirect estimates of long-term growth trends. Thus, it is unclear whether modern growth rates are similar to those in the past. In one recent study, McCarthy (2003) showed that while annual growth varied within and between *Rhizocarpon* thalli, linear extrapolation of mean annual growth rates collected over a 4-year period closely matched century-long growth as estimated by a lichen growth curve that was developed from measurements on historical and tree-ring dated surfaces. This finding shows that while tedious and time consuming, repeated measurement and linear extrapolation of growth rates can, in some cases, provide a reasonably accurate way to calibrate a lichen growth curve.

Workers should also note that measurements of growth rate derived by one approach (e.g., direct measurement to painted markers) are not interchangeable with measurements done using another approach (e.g., repeated measurement of change along random radii). Figure 2 and Tables 1 and 2 illustrate this. Despite this and other concerns (e.g., small sample sizes, accuracy and precision of the measurement method), repeated measurement of lichen growth and the establishment of

long-term monitoring plots are the only way to generate true growth rate data that can be used to address some of the substantial questions that remain about the nature of growth rates at various stages in the lichen life cycle (e.g., Armstrong, 1983; Armstrong and Smith, 1987). Direct measurement may also be the only way to calibrate lichen growth curves in remote regions where dating controls are unavailable.

Lichen 'Growth Curves'

The term 'growth curve' is an unfortunate misnomer. It was introduced to lichenometry in Roland Beschel's early work to describe the long-term radial growth trend in crustose lichens. Beschel estimated this growth trend as being a curved line on a lichen size-age scattergraph. This curved line is readily produced using 'traditional' and some statistical approaches to lichenometry (e.g., the fixed quadrat or the fixed-area largest lichen (FALL) approach to lichenometry: Bull and Brandon, 1998; Savoskul and Zech, 1997). However, lichen growth rates estimated by some statistical approaches to lichenometry tend to plot as straight lines. Linear growth 'curves' result when only older control points (e.g., >100 years) are used or if researchers use assumptions underlying randomized sampling designs and linear regression analysis (e.g., Matthews, 1974; McCarroll, 1994).

In general, lichenometrically useful species begin growth after a colonization lag interval (ecesis) that can be as short as a decade or longer than a century at some micro sites. Initially, there is a phase of rapid radial growth (sometimes described as logarithmic growth or the 'great period,' e.g., Beschel, 1950). This phase lasts for a few decades. A prolonged period of steady, linear growth follows and may last for centuries. While it is unknown how long an epilithic lichen thallus can live, growth curves calibrated using radiocarbon ages of buried organics are sometimes used to estimate lichen growth at the surface of deposits that are several thousand years old (e.g., Miller and Andrews, 1972). Growth curves constructed in this way give the false impression that individual lichens can live for millennia and that even in old age, thallus growth rates never drop to zero. Instead, the finding of large thalli with nearly circular outlines on old surfaces should be seen as circumstantial evidence of lichen life spans. Some exceptionally large lichen thalli are genetically complex mosaics. The weathering and loss of the central part of large lichen thalli is common in old age and such areas can be recolonized in such a way that new and old parts of the thallus become indistinguishable. While old and potentially useful as indicators of substrate age, these thalli may not be individuals in a genetic or biological sense. Similarly, extrapolation of growth rates beyond control points and/or from short-term measurements is a questionable way to 'model' growth rates. However, the apparent scarcity of acceptable alternatives calls attention to the need for greater empirical research in this regard.

The 'Traditional' Approach to Lichenometry

Roland Beschel and early practitioners of lichenometry used a simple search and measurement strategy to indirectly estimate lichen growth rate. This 'traditional' approach involves a

Figure 2 Comparative photographs show marked lichen thalli in the summers of 1996 (a) and 2006 (b). The original photographs (right) have been paired with a bitmap of each photograph (left). Painted crosshairs surround thallus #76 (A–E, see above right) and provide fixed points where digital calipers were used to measure distances between the crosshairs and the thallus margin. The lines shown on the bitmaps (a and b, see above left) show six randomly chosen diameters (12 radii) where change in thallus size was photogrammetrically measured. These illustrations and the data in [Tables 1](#) and [2](#) show that the shape and growth of these thalli is not well represented by change in a single radius or diameter. Use of the mean of 12 radii or five control points should ensure that the growth indices are representative (see [Tables 1](#) and [2](#)). Users of lichenometry should, but do not, quantify thallus circularity, thallus area or thallus perimeter.

complete search of all exposed surfaces on a deposit and the measurement of the diameter of a few of the largest lichens in the search area. In some cases, parts of a landform may be searched and analyzed as separate units. This is especially common in the dating of moraine complexes at valley glaciers where individual morainic ridge segments have been crosscut by streams or are suspected of having proximal or distal surfaces that became ice-free and stable at different times.

In order to construct a lichen growth curve using the traditional approach, several growth ‘control points’ are developed using scatterplots that match the sizes of the largest lichen thalli with the known ages of their substrates. The substrates are considered to be growth control surfaces and their ages are known by independent dating methods (e.g., tree-ring dating, archival documents or photographs, etc.). The resulting data (control points) are used to calibrate/estimate the radial growth trend over the longer term. A growth trend line is then fit to the points by eye so that accepted control points fall on the line. Subjective judgments rather than statistical tests are used to decide which points are anomalous and which best reflect the maximum growth rate of thalli in mesic or xeric habitats ([Figure 3](#)). As the likelihood of finding a larger thallus tends to increase as microhabitat variety and search area

size increases, greater trust is generally placed in larger control surfaces. Tombstones, buildings, and monuments are sometimes used as lichen growth control points, but they are often at lower elevations than where lichenometry will be used and may not closely reflect rates of lichen establishment and growth in the alpine. Accordingly, authors usually provide careful descriptions and evaluations of each control point and explain why they accept or reject them. The traditional approach to lichenometry involves a thorough (complete) search of all surfaces on a landform unit. Lichens in moist and mossy sites are either not measured or are measured for comparative purposes and excluded as anomalous. In the traditional and other approaches to lichenometry, thalli with circular outlines are assumed to be individual lichens that arose by radial growth from a single point. Despite the fact that most epilithic lichens infrequently have perfectly circular thallus outlines, users of lichenometry assume that noncircular thallus outlines are ‘irregular’ and must have formed by the merger of neighboring thalli, violating at least one of the basic assumptions of lichenometry.

Since Beschel’s first use of lichenometry in glacier forefields, the search and measurement strategies and the data reporting formats used in the traditional approach to lichenometry have

Table 1 Raw measurement data obtained for one thallus (#76) shown in [Figure 2](#). A random number generator was used to select six angles at which the radius would be measured in the upper half of the thallus. These radial lines were extended into the lower half of the image to make a total of 12 radii where measurements were taken. The distance along each radius was first measured in pixels with the Ruler tool in Adobe® Photoshop® CS2. Distances in pixels were converted to millimeters by dividing pixel distances by the resolution of this image (944.882 pixels per cm) and multiplying by 10. As this image was at 1/3 life size, the raw values for radius distance, area, and perimeter were then multiplied by this scale factor (3) to convert to life size. These data are for illustrative purposes only. Space limitations do not permit a full articulation of the methods used to eliminate distortion and validate measurement accuracy and precision. Note that the 1999 data are used because, as [Figure 2](#) shows, thallus #76 had merged with nearby thalli in 2006

Year	Random no. (angles)	Radius distance (pixels)	Raw radius distance (mm)	True radius distance (mm)	Area (cm ²)	Perimeter (cm)	Circularity	Scale factor
1996	12	269.87	2.86	8.57	0.84	14.64	0.15	3

	340	317.39	3.36	10.08				

Table 2 Comparison of thallus growth data photogrammetrically measured using ImageJ software at 12 radii and measurements done in the field using digital calipers and five fixed points. The means are similar, but there is a wide scatter in the data. The growth (of thallus #76, [Figure 2](#)) is not well represented by any one radius or by measurement to any one fixed point. Note that these data cover a 3-year growth interval, not the 10-year interval shown in [Figure 2](#)

Calipers			ImageJ		
Number of measurement points (fixed points)	Mean growth (mm)	Standard deviation (mm)	Number of measurement points (random sample of radii)	Mean growth (mm)	Standard deviation (mm)
5	1.29	0.43	12	1.47	0.51

become somewhat standardized. By the mid-1970s, it became common practice to report the mean size of five or more of the largest thalli on individual moraine segments and size differences of 10–20% between the largest thalli became an accepted way to identify/accept/reject thalli (e.g., [Benedict, 1967](#); [Webber and Andrews, 1973](#)). This continues today with flexible plastic rulers or calipers used to measure the maximum diameter, minimum diameter, and the longest and/or the shortest axis of thalli as the index of age. Over the years, it has also become accepted practice to measure thalli that belong

to broad, morphologically similar, aggregated species groups (e.g., *Rhizocarpon geographicum* agg.; [Innes, 1985](#)). This is clearly a disturbing source of error if some of the aggregated species grow at different rates and are indistinguishable in the field. However, the use of species aggregates is often a practical necessity because positive identification of crustose lichens to the species level involves the use of chemical stains and microscopic examination of spores ([Benedict, 1988](#)).

Typically, lichen size data are summarized using tables and maps that show where the size data were collected on each

Figure 3 Nitrogen from the feces of rodents and birds has created a dense lichen cover of *Xanthoria elegans* (Link) Th. Fr. and other nitrophilous lichen species on these granitic rocks in Canada's Northwest Territories. Most other rocks in this area have only one or two lichen thalli. Such sites are easily identified in the field and are excluded from lichenometric searches.

landform (e.g., showing lichen sizes on the proximal vs. the crest or distal slope of a moraine). Growth curves derived using this traditional approach seldom extend for more than three centuries. The curved (nonlinear) growth curve, the complete search strategy, the use of a single largest thallus as a control point, and simple descriptive statistics are hallmarks of the traditional approach.

It would seem that when carefully executed, the traditional and statistical approaches to lichenometry provide equally acceptable and accurate age estimates (e.g., [Karlén and Black, 2002](#)). However, each approach has its advantages and limitations. For example, the traditional approach is not well suited to situations that require an exhaustive search of large areas or where there is a need to establish minimum ages for episodic or sequential events that intermix old and newer materials (e.g., as occurs in seismically triggered rockfalls and in debris flows). However, the traditional approach is well suited to the study of small- or moderate-sized morainic ridge complexes at alpine glaciers and perhaps the only approach that has been successfully used in carbonate terrain.

Statistical Approaches to Lichenometry

Statistical approaches to lichenometry use parametric statistics not only to characterize, but also to infer thallus sizes with reference to an ideal (statistically normal or normalized) distribution of thallus size data. Many researchers have used

random, stratified random or plot-based sampling designs and parametric statistical tests to develop lichen growth curves and assign lichenometric ages. These approaches generate reproducible and, in some cases, highly accurate age estimates with well-defined errors of the estimate (e.g., [Bull and Brandon, 1998](#)).

There are many strengths and potential advantages of using a statistical approach to lichenometry. For example, the use of replicated plots (e.g., 10 m × 10 m plots) makes it possible to collect representative samples for large areas and facilitate comparisons within and between study sites. Statistical approaches have also seen considerable use in the dating of large glacier forefields (e.g., [Larocque and Smith, 2004](#)), development of growth curves representative of broad regions (e.g., [Solomina and Calkin, 2003](#)), and paleoseismic applications (e.g., [Bull and Brandon, 1998](#)) where individual blocks were displaced by earthquake-generated rockfalls. While assumptions about thallus growth are generally unchanged from those used in the traditional approach to lichenometry, some assumptions are adjusted or added in order to satisfy the requirements of statistical tests (e.g., each thallus has an equal opportunity of being measured, a normal distribution of measurement error exists across the population, etc.).

Most statistical approaches to lichenometry have used linear regression to plot growth curves, but methodologies can widely differ in their sampling designs. For example, estimates of deglaciation dates have been derived using a stratified random sampling design with or without nested quadrats

(e.g., Matthews, 1994), and transects and plots are sometimes located along the center line of glacier retreat (e.g., Larocque and Smith, 2004). In paleoseismic work with the FALL sampling design (e.g., Bull and Brandon, 1998), sampling is restricted to smooth rock surfaces on boulders of a fixed size. This reduces the amount of variance that may be due to microtopography and microhabitat. The FALL method also assigns a subjective rank to thallus shape/regularity and assigns statistical confidence intervals so as to define the upper and lower range of the FALL estimated ages. The assumption that lichen communities (cohorts) usually have a unimodal distribution of thallus sizes allows users of the FALL approach to statistically smooth (normalize) lichen size distributions and assign ages to thallus size distributions. Unfortunately, these assumptions have not yet been supported by robust biological data sets.

Practical Suggestions and Concerns About Lichenometry

The credibility of lichenometry as a dating technique is being eroded as author after author ignores the need to validate the accuracy and precision of thallus measurements, species identifications, and sampling thoroughness. Analytical chemists routinely use certified reference materials and repeated tests to calibrate their analyses. Why do users of lichenometry not use data and simple tests to quantitatively define their measurement accuracy and precision, and verify the certainty of their species identifications? Lacking accuracy and precision data, how would we know if our ages, models, and assumptions were precisely wrong? Perhaps the biggest challenge we face in lichenometry is the lack of scientific rigor. It would seem that authors/editors and readers do not ask or seek answers for such basic questions as: How reproducible is this sampling method? Has the author and/or journal reported and archived enough information to ensure that another worker can easily find and resample/rephotograph these thalli and independently test the findings? Has the author provided sufficient data to demonstrate the accuracy and precision of thallus measurements? Has the author adequately demonstrated that (e.g., 90%) of the lichens were properly identified to species or group level? There are many ways by which we might improve the scientific rigor of lichenometric work. For example, certified reference material could be circulated and used to determine how well individual workers can positively identify lichens to species or group level, thalli of known dimensions could be used to ascertain the accuracy and reproducibility of photogrammetric work, and data repositories could be used to archive complete data sets and facilitate follow-up studies by independent workers. With the possible exception of archival storage, these things are not yet part of our research culture. However, workers could, at the very least, do repeated measures of marked thalli on different days and use descriptive statistics to show the variability in measurements within and between operators. Species identification success rate could also be assessed if workers collected and identified more than a few voucher specimens and reported the success of their species identification as compared to the identifications made by a paid, professional lichenologist. If these suggestions are followed, we might learn whether

workers in some areas have greater success or are more skilled in their identification of lichen species, and/or if measurement and identification errors vary with thallus size or on landforms of different age. Statistical procedures should also be turned inward so that workers evaluate and report on the likelihood that untested and unknown errors invalidate their findings.

My final observations focus on the use and misuse of the words 'growth curve.' The only true growth curves are plots that depict changes in the size of thalli that have been repeatedly measured in the same way at the same locations over successive years. As diametric growth is not uniform along any axis in nonplacoidial thalli (e.g., the yellow-green *Rhizocarpon*s), our ability to find and precisely remeasure a diameter (or radius) is challenged by shape changes at the thallus margin. If workers claim that they have accurately measured a diameter, then they must use data and tests to show that this same diameter measure can be reproduced to an acceptable accuracy and precision (e.g., on other days). Long-term studies face major challenges. They must prove that their diameter measure is highly reproducible in the short term and that the measure is accurate and highly reproducible at the decadal scale. Reliance on one or two thallus diameters as an index of thallus growth is tenuous and foolhardy. Diameter data are meaningless if we do not know how circular the thallus outline is/was at the time of measurement. Lacking this information, how can we determine the representativeness of diametric data and how can a worker justify its use? Ultimately, workers, readers, and editors must realize that the use of unvalidated and unrepresentative data sets can lead to precisely the wrong conclusions.

Future Directions in Lichenometry

Lichenometry is an inexpensive, widely adaptable, and invaluable tool for use in estimating surface ages in lichen-dominated landscapes. Its continued use is virtually guaranteed as is the likelihood that users will ignore critics and continue to use unvalidated measurements to generate unvalidated ages. In this digital age, it seems reasonable to suggest that the future will see increased use of digital imaging and/or customized computer software to assist in the development of 'growth curves.' Perhaps with concomitant advances in lichenology, we may gain better insights into some questions: Why are growth curves curved? What is the maximum life span of a *Rhizocarpon* thallus? Does the presence/absence of certain lichen species clearly indicate surface age? Are modern growth rates identical to those in the recent past? Unfortunately, history suggests that users of lichenometry will not soon provide substantive answers to these basic questions.

Loess Deposits: Origins and Properties

Introduction

Loess is an eolian (windblown) sediment that is an important archive of Quaternary climate changes. It may provide one of the most complete terrestrial records of interglacial–glacial cycles. Loess is unusual as a record of Quaternary climate change because it is one of the few sediments that is deposited directly from the atmosphere. Thus, it is a geologic deposit that contains a record of atmospheric circulation and can be used to reconstruct synoptic-scale paleoclimatology. Loess is also unusual in that it can be dated directly using ‘trapped electron’ or luminescence methods that require only the sediment itself. Commonly, loess deposits are not homogenous sediments, but most contain buried soils, or paleosols. It is the combination of both unaltered loess deposits and intercalated paleosols that gives this sedimentary record much of its richness as a Quaternary paleoclimate record.

Definition of Loess

Loess can be defined as sediment that has been entrained, transported, and deposited by the wind and is dominated by silt-sized (50–2 μm diameter) particles. Most loess deposits are not composed completely of silt, but also contain measurable amounts of sand (>50 μm) and clay (<2 μm). Nevertheless, loess typically has 60–90% silt-sized particles. To distinguish loess from fine-grained (aerosolic) dust that may have a subtle presence within soils or sediments, loess should be recognizable in the field as a distinctive sedimentary body. It commonly forms a mantle or cover on preexisting landscapes and can be anywhere from a few centimeters to several hundred meters in thickness.

Unlike eolian sands, fluvial sediments, or marine sediments, primary structures in loess are subtle. Some loess deposits have primary bedding structures, such as faint, horizontal laminations and, less commonly, cross-bedding. Many loess deposits are characterized by a massive (as opposed to ‘loose’ or structured) condition. Interparticle binding by clays and/or carbonates often results in considerable material strength and explains the ability of loess deposits to form vertical faces along river or stream banks and road cuts. In fact, some European researchers regard this weak cementation by carbonate as a process called ‘loessification,’ a prerequisite for a sediment to be considered true loess. Most other researchers do not have such a restricted definition of loess, however, and regard all eolian silt that forms

a distinct sedimentary body as loess (Muhs and Bettis, 2003; Pye, 1987). Secondary structures in loess are more common than primary structures, and consist of fractures, burrows, rhizoliths (root casts composed of iron oxides or carbonate), carbonate nodules or concretions, oxidation or reduction streaks or bands, and paleosols. Although mammal fossils are sometimes found in loess deposits, the most common fossils are shells of land snails, which can be powerful paleoclimatic tools (Rousseau and Kukla, 1994).

Spatial Distribution of Loess

Loess covers a significant amount of the Earth’s land surface, perhaps as much as 10% (Pye, 1987). Because of its widespread distribution and favorable texture and mineralogy, it forms some of the world’s most important agricultural soils. In the Eastern Hemisphere, loess is abundant over much of Eurasia (Figure 1). Most loess in Eurasia is distributed in a latitudinal belt between about 40° and 60° N, covering areas south of the limits of continental or mountain glaciers of Quaternary age in western and central Europe, Russia, and Central Asia (Frechen et al., 2003; Pye, 1987; Rozycki, 1991). An important exception is China, where loess covers large areas at lower latitudes that were not near continental ice sheets, mountain ice caps, or valley glaciers (Liu, 1988). Loess is largely absent from subtropical and tropical latitudes of Eurasia.

In the Western Hemisphere, loess is present in both North and South America (Figures 2 and 3). In South America, there are two major loess belts, the Pampas loess in central Argentina and the Chaco loess in northern Argentina; less-certain loess deposits may be located in Bolivia, Paraguay, Uruguay, and Brazil (Zárate, 2003). In North America, loess is found in Alaska and adjacent Yukon Territory (Péwé, 1975), the Palouse area of eastern Washington and adjacent Oregon (Busacca et al., 2004), the Snake River Plain and adjacent uplands of Idaho, the Great Plains region east of the Rocky Mountains, and the greater Mississippi River drainage basin (Bettis et al., 2003). Loess bodies of the North American midcontinent appear to be continuous at small scale. At a larger scale, it is apparent that these loess bodies have very different thickness trends that are not part of a larger regional trend (Bettis et al., 2003; Muhs and Bettis, 2003). The variability of loess thickness over a landscape is, however, one of the most powerful tools in using this sediment for paleoclimatic reconstructions.

Figure 1 Map showing the distribution of loess in Eurasia and localities or regions referred to in the text. Compiled from Rozycki (1991) and Liu (1988), and redrawn from figure in Muhs and Bettis (2003).

Loess is not extensive over Africa, nor is it widespread in adjacent subtropical parts of the Middle East. There are, however, well-documented, but geographically limited areas of loess in Tunisia, Libya, Nigeria, Namibia, and Israel (Figure 1). Loess is also largely absent in Australia, although there are areas of fine-grained eolian mantles and considerable evidence of exotic quartz in soils (Hesse and McTainsh, 2003). However, loess is found over much of New Zealand, where its stratigraphy (e.g., Berryman, 1993) and distribution (Eden and Hammond, 2003) have been studied in considerable detail.

Mineralogy and Geochemistry of Loess

Most loess deposits have a mineralogy that includes quartz, plagioclase, K-feldspar, mica, calcite (and sometimes dolomite), and phyllosilicate clay minerals (smectite, chlorite, mica, and kaolinite). Heavy minerals are usually present, but in small amounts. Bulk geochemical studies show that the dominant constituent in loess is SiO_2 , which ranges from ~45% to 75%, but is typically 55–65%. The high SiO_2 contents of loess deposits reflect a dominance of quartz, but smaller amounts of feldspars and clay minerals also contribute to this value. Plots of SiO_2 versus Al_2O_3 show that most loess has a composition that falls between that of average shale and quartz-dominated sandstone (Muhs and Bettis, 2003). Loess

with high clay mineral content has more Al_2O_3 , Fe_2O_3 , and TiO_2 ; loess with higher carbonate (calcite and dolomite) content has more CaO and MgO .

Loess Origins: Processes of Silt Particle Formation

A traditional view of loess is that silt-sized particles are produced mostly by glacial grinding of crystalline rocks, deposited in till, reworked by fluvial processes as outwash, and finally entrained, transported, and deposited by wind (Figure 4). This classical model of loess formation has led to the view that loess deposits are primarily markers of continental-scale (global) glacial periods. The model is supported by observations of the geographic proximity of loess bodies to the southern limits of the Laurentide ice sheet in North America (Ruhe, 1969) and the Fennoscandian ice sheet in Europe (Frechen et al., 2003), as well as smaller glaciers in Asia (Dodonov, 1991) and South America (Zárate, 2003). In the 1950s and 1960s, widespread application of radiocarbon dating showed that the youngest loess deposits in North America coincided with the ages of the last major expansion of the Laurentide ice sheet (Ruhe, 1969). More recently, many luminescence ages show that the youngest loess dates to the last glacial period in Europe as well (Frechen et al., 2003).

Despite the long-term support for the classical 'glacial' concept of loess formation, there have been challenges to this

Figure 2 Map showing the distribution of loess and eolian sand in southern South America. Redrawn from Zárate (2003) and sources therein.

model going back at least 50 years. The debate has continued to this day and centers on the issue of 'glacial' loess versus 'desert' loess (Muhs and Bettis, 2003; Smalley, 1995; Wright, 2001). 'Desert' loess is a term used loosely to describe eolian silt generated in and derived from arid or semiarid regions that were not glaciated. The debate on desert loess versus glacial loess centers on whether silt-sized particles can be produced by mechanisms other than glacial grinding; specifically, whether or not they can be produced in deserts. A variety of mechanisms can, in principle, produce silt-sized particles in arid regions and these are summarized in a highly simplified model (Figure 5). These processes include frost shattering, comminution (particle size reduction by crushing or grinding) by fluvial and mass-movement transport, chemical weathering, salt weathering, eolian abrasion, and ballistic impacts.

China is the region most often cited as the best example of a long-term and spatially extensive nonglacial (or 'desert') loess record. The observations cited for a desert origin are loess thickness and particle size trends that show decreases downwind of desert basins. In addition, modern dust storms originate in the same desert basins. However, loess in China may have, as its ultimate source, glacially derived silt. The mountains surrounding the largest desert basins in China have glaciers at present and were more extensively glaciated in the past. It is possible that much primary silt production

Figure 3 Map showing the distribution of loess in North America, from compilations in Péwé (1975), Bettis et al. (2003), and Busacca et al. (2004), and references therein.

takes place by glacial grinding (as well as other processes) in the mountains, and outwash may carry the silts into the basins (Smalley, 1995). The silts are then transported from the desert basins by wind. If this model is correct, then the arid basins are simply reservoirs for particle storage and have little to do with silt production itself, a concept supported by geochemical and isotopic data (Sun, 2002).

Despite continuing controversy over whether loess in China is of 'glacial' or 'desert' origin (or both), it does appear that the main periods of loess sedimentation in China correspond to glacial periods, whereas periods of soil formation (when loess deposition appears to cease) correspond to interglacials or interstadials (Kukla and An, 1989; Porter, 2001; Shen et al., 1992). Indeed, the loess-paleosol record of China can be reasonably well correlated with the deep-sea sediment oxygen-isotope record of glacials and interglacials (Figure 6). Nonglacial loess in the Great Plains of North America is also dated to the last glacial period (Aleinikoff et al., 1999; Maat and Johnson, 1996; Muhs et al., 1999; Roberts et al., 2003). These observations suggest that even in regions where glacial sediment may not have been abundant as a loess source, glacial periods may be favorable times for eolian silt availability, entrainment, transportation, and deposition. Glacial-period factors that may have favored loess entrainment and transportation include decreased vegetation cover, increased aridity, increased wind strength, and a decreased intensity of the hydrological cycle, such that silt can stay in suspension for longer distances (Kohfeld and Harrison, 2000; Mahowald et al., 1999).

Figure 4 Classical model of ‘glacial’ loess formation wherein silt-sized particles are produced primarily by glacial grinding, delivered to outwash streams and finally entrained by wind. Redrawn from [Muhs DR and Bettis III EA \(2003\)](#) Quaternary loess-paleosol sequences as examples of climate-driven sedimentary extremes. *Geological Society of America Special Paper* 370: 53–74.

Figure 5 Model of ‘desert’ loess formation wherein silt-sized particles are produced by a variety of nonglaciogenic processes before eventual entrainment by wind. Redrawn from [Muhs DR and Bettis III EA \(2003\)](#) Quaternary loess-paleosol sequences as examples of climate-driven sedimentary extremes. *Geological Society of America Special Paper* 370: 53–74.

Figure 6 Loess stratigraphy at Luochuan, China (Kukla and An, 1989) and correlation with the deep-sea oxygen-isotope ($\delta^{18}\text{O}$) record of equatorial Pacific core V28-239 (Shackleton and Opdyke, 1976). Periods dominated by loess deposition ('L' units) occur during interglacials and periods dominated by soil formation ('S' units) occur during glacials. Correlations are based on ^{10}Be accumulation in loess and paleosols at Luochuan (redrawn from Shen C, Beer J, Liu T, et al. (1992) ^{10}Be in Chinese loess. *Earth and Planetary Science Letters* 109: 169–177) and identification of the Brunhes–Matuyama (B/M) boundary at 50.5 m at Luochuan and at 726 cm in V28-239. Approximate ages in V28-239 are based on the depth of the B/M boundary (~780 ka) and an assumed long-term average sedimentation rate of $\sim 0.93 \text{ cm ka}^{-1}$.

Loess Stratigraphy

Loess stratigraphy is rarely simple. Although loess is sometimes conceptualized as a thick accumulation of unaltered, massive silt, in reality it is usually sediment that has experienced varying degrees of weathering and pedogenesis (soil-forming processes). Some workers have pointed out that loess sedimentation and soil formation are essentially competing processes: when loess sedimentation rates are high, pedogenic processes cannot keep up and relatively unaltered sediment accumulates (Muhs et al., 2004; Verosub et al., 1993). When loess sedimentation rates are low, soil-forming processes extend deeper into previously deposited loess, but soils may also continue to accumulate small amounts of eolian sediment during pedogenesis. Thus, loess sequences should not be viewed in the same way as other Quaternary records, such as deep-sea or lacustrine sediments, where a better case can be made for more or less continuous sedimentation.

One distinct advantage of loess over many other Quaternary sediments is that it can be dated directly, using luminescence methods (Aitken, 1998). Because of the decay of naturally occurring radioelements in surrounding sediment, electrons are trapped in defect areas in minerals such as quartz and feldspar. These electron traps are effectively emptied, or 'zeroed' when sediment is entrained by wind and exposed to sunlight. In the case of optically stimulated luminescence, the traps are emptied and therefore the signal is zeroed usually in a matter of seconds to minutes. After deposition and sediment burial, radiation, largely from naturally occurring elements (potassium (K), rubidium (Rb), uranium (U), thorium (Th)) within the sediment itself, excites electrons and causes them to be trapped again within the crystal structures and defect areas of minerals. Subsequent stimulation in the laboratory by optical or thermal sources causes luminescence as the trapped electrons are released. The amount of luminescence is a function of the total radiation dose to which the mineral has been exposed. Because the natural annual environmental dose rate can be calculated from the concentrations of K, Rb, U, and Th within the sediment, it is therefore possible to determine the time the sediment was last exposed to sunlight. Luminescence dating is ideal for loess deposits because unlike other dating methods, no fossils or organic materials are required; the minerals of choice (quartz and feldspar) are common in loess; being eolian sediment, it is effectively zeroed; and dating is possible back to 60–100 thousand years ago (ka). Errors are typically of the order of 5–10% (e.g., Roberts et al., 2003), but tend to increase as the limit of the technique is approached.

Loess, as a representation of the glacial record, has been studied extensively in Europe and North America. Decades of study and dating have established a clear link between the loess record and glacial–interglacial cycles. The modern soils of much of Europe have been developing since the end ($\sim 13 \text{ ka}$) of the last ('Weichshelien' or 'Würm') glacial period. Hundreds of luminescence ages confirm that the uppermost loess in Europe was deposited during the Weichshelien–Würm glacial period, from ~ 28 to $\sim 13 \text{ ka}$ (Frechen et al., 2003). Loess from this period is well displayed as relatively unaltered sediment in many exposures, such as the classical section near Kesselt, Belgium (Figure 7), described in detail by Vandenbergh et al. (1998) and Van den Haute et al. (1998). This last glacial loess has an equivalent in North America that is called Peoria Loess (Figures 8 and 9). Weichshelien loess is, in turn, underlain by a minimally developed paleosol (LH, or 'Limon Humifère') that may have its equivalent in North America as the Farmdale 'Geosol' (=paleosol) and Gilman Canyon Formation (the upper part of which contains a paleosol). In Europe, a well-developed soil, the Rocourt paleosol, is found below the LH paleosol and formed during the last interglacial period. This soil has its equivalent in North America as the Sangamon Geosol. Both the Rocourt paleosol and Sangamon Geosol probably developed over tens of thousands of years during a long interglacial period with little loess sedimentation. The Rocourt paleosol, in turn, is developed in loess of the penultimate glacial period ('Saalien'), which has its equivalent in North America as the Loveland Loess. The age of penultimate glacial loess on both continents may be on the order of around 160–140 ka (Forman and Pierson, 2002; Maat and Johnson, 1996).

Figure 7 Photograph of loess and paleosols representing the last interglacial–glacial cycle exposed in brickyard near Kesselt, Belgium (see [Van den Haute et al., 1998](#) and [Vandenberghe et al., 1998](#)). Photograph by D.R. Muhs.

In nonglacial environments, loess stratigraphy is generally similar to that of glacial regions. Thus, even where glacial silt is not the primary sediment source, loess deposition occurs primarily during glacial periods and soil formation occurs primarily during interglacial periods. In Central Asia ([Dodonov, 1991](#)) and in the Great Plains region of North America ([Aleinikoff et al., 1999](#)), loess is derived from both nonglaciogenic and glaciogenic sources. Nevertheless, many of the same stratigraphic units have been identified and correlated with loess sequences near continental ice. In Central Asia, for example, the main episodes of loess deposition were during the last two glacial periods ([Frechen and Dodonov, 1998](#)). In the Great Plains of North America, Peoria Loess, a Farmdale-equivalent soil (a paleosol in the Gilman Canyon Formation), the Sangamon Geosol, and Loveland Loess have all been identified ([Figure 9](#)). Last glacial (Peoria) loess in North America also has its equivalent as the ‘Malan’ or ‘L1’ loess in China, although Malan Loess spans a longer period of time and includes what in North America would be called the Roxana Silt or the Gilman Canyon Formation. The last

interglacial soil complex (the Sangamon Geosol of North America) is called the ‘S1’ paleosol in China; it is developed in the ‘L2’ loess, which is roughly equivalent to Loveland Loess in North America.

There are, however, exceptions to the generalization of loess deposition occurring only in glacial periods. For example, there is well-documented evidence of Holocene loess in China (see [Roberts et al., 2001](#), for a recent example) and in North America, both in the Great Plains (e.g., [Miao et al., 2005](#)) and Alaska (e.g., [Muhs et al., 2004](#)). In other regions, it is difficult to correlate loess deposition and soil formation with specific glacial and interglacial periods. For example, in Israel, desert loess and fine-grained dust are thought to have been deposited over much of the Quaternary ([Dan and Yaalon, 1971](#)), probably during both glacials and interglacials. Soil formation seems to take place syndepositionally, that is, concurrently with loess deposition. In this area, relatively unaltered loess is, therefore, not apparent in most stratigraphic sections; clay-rich (Bt) horizons form in the loess and calcic (Bk) horizons form below the Bt horizons. Nevertheless, stratification is

Figure 8 Photograph of loess and paleosols representing the last interglacial–glacial cycle exposed on the north end of Crowley's Ridge, Arkansas, USA (see Markewich et al., 1998). Photograph by D.R. Muhs.

Figure 9 Photograph of loess and paleosols exposed in the Elba canal cut, eastern Nebraska, USA (see May et al., 1995). Note paleochannel cut into the Gilman Canyon Formation, Sangamon Geosol, and Loveland Loess, filled by Peoria Loess. Photograph by D.R. Muhs.

apparent in these sections, and several cycles of loess deposition/soil formation can be seen in outcrops (Figure 10).

The stratigraphy of loess–paleosol sequences can sometimes be used as a relative dating tool. In China, the sequence of loesses (S0, L1, S1, L2, etc.) is so readily identifiable, it can be used as a relative dating or correlation tool for stream terraces when these landforms are mantled with loess (Porter

et al., 1992). In New Zealand, loess deposits, tephras, and paleosols have an increasingly complex record on successively older marine terraces (Berryman, 1993). The oldest marine terraces have the most complete succession of loess deposits, tephras, and paleosols (Figure 11). Younger marine terraces have only the upper part of the record, and the youngest marine terrace is not overlain by loess at all.

Figure 10 Loess deposits with calcic-horizon-bearing paleosols, northern Negev Desert, Israel (see [Dan and Yaalon, 1971](#)). Photograph by D.R. Muhs.

Quaternary Paleoenvironmental Information from Loess Sequences

There is a wide variety of paleoenvironmental information that can be obtained from loess–paleosol sequences. Loess itself, as its properties change over a landscape, can yield important

clues about the paleowind that deposited it. Loess thickness, particle size, and carbonate content generally decrease away from the source ([Bettis et al., 2003](#); [Liu, 1988](#); [Mason, 2001](#); [Muhs and Bettis, 2003](#); [Muhs et al., 2004](#); [Porter, 2001](#); [Ruhe, 1969](#); [Smith, 1942](#)). The decrease in loess thickness reflects a reduction of sediment load downwind from the source, the

Figure 12 Thickness, coarse silt content, and carbonate content of Peoria (last glacial) Loess as a function of distance southeast of the Illinois River, IL, USA. Data from Smith (1942); regression equations computed by D.R. Muhs.

decrease in mean particle size reflects winnowing of the coarse load, and the decrease in carbonate content reflects syndepositional leaching downwind, where deposition rates are lower. If a loess source were a north-to-south-trending river valley, a decrease in loess thickness and mean particle size to the east of the river would imply northwesterly, westerly, or southwesterly paleowinds (Figure 12), at least during those periods when winds were strong enough to transport silt-sized particles.

Loess lacks many of the Quaternary paleoecological indicators that are commonly used in lacustrine or marine sediments, such as pollen, diatoms, Ostracoda, Radiolaria, or Foraminifera. Furthermore, it is rare for mammal fossils to be preserved in loess. However, it is common for the shells of land snails to be preserved in loess, and they are abundant in China, Europe, and North America. Most or all of these snails are extant species, and their modern zoogeography is reasonably well established.

Thus, it is possible to infer past climates during the times of loess deposition by identification of extralimital taxa, that is, those species that do not presently live at a locality where they are found as fossils. In North America, the upper part of last glacial loess of the central Great Plains contains several extralimital boreal or Cordilleran species of snails (Figure 13). The presence of these northern-forest and mountain-forest species implies a much cooler-than-present last glacial climate with forest vegetation, as opposed to the present, temperate grassland of the region (Rousseau and Kukla, 1994).

Whereas sedimentologic and paleontologic data in loess give information about glacial periods, paleosols within loess deposits yield information about interglacial or interstadial periods. Without question, the most common method applied to loess-derived paleosols since the 1980s has been the measurement of magnetic susceptibility and other mineral magnetic properties (Kukla and An, 1989; Maher et al., 1994; Porter, 2001; Porter et al., 2001; Verosub et al., 1993). Magnetic susceptibility is essentially a measurement of the abundance of magnetic minerals such as magnetite, a primary, rock-forming mineral, and maghemite, a secondary, pedogenic mineral. Other minerals, such as hematite, have very low but measurable magnetic susceptibility that can be differentiated from magnetite and maghemite. Measurement of these properties is rapid, inexpensive, and highly reproducible. Numerous studies have shown that Chinese loess has relatively low magnetic susceptibility and intercalated paleosols have high susceptibility. This makes the technique highly valued as a section-to-section correlation tool (Kukla and An, 1989) and many researchers have extended the method to correlation with deep-sea oxygen-isotope records. Other researchers have attempted to develop transfer functions, correlating magnetic susceptibility in modern soils with climate parameters, such as mean annual precipitation (Maher et al., 1994). If the assumptions are valid in this approach, then it would, in principle, be possible to estimate past climate from magnetic susceptibility of paleosols in loess. However, several problems arise with this approach. One is that magnetic susceptibility in modern, loess-derived soils in China is partly a function of particle size and sediment accumulation rate (as a dilution effect), as well as climate. Both these factors are spatially variable but highly correlated with one another (and climate) across the Chinese Loess Plateau (Porter et al., 2001). Another problem is that transfer functions of magnetic susceptibility and climate assume that soils quickly reach a steady state with regard to pedogenic magnetic mineral production. Soil chronosequence studies, however, show that magnetic susceptibility in soils continues to increase over time (Singer et al., 1992). Finally, in some regions, magnetic susceptibility trends are the reverse of what they are in China. In Siberia and Alaska, for example, susceptibility is highest in loess and lowest in paleosols, due to high-magnetite loess sources and little or no production of secondary maghemite in soils (Begét et al., 1990; Chlachula, 2003). Undoubtedly, part of the attraction of using magnetic susceptibility in studying loess and paleosols is the relative ease, rapidity, and low cost of analysis. Nevertheless, it is important to remember that in addition to the problems just summarized, magnetic minerals constitute a very small portion of the mineral suites of loess and its paleosols.

Figure 13 Stratigraphy of last glacial (Peoria) loess at Eustis, Nebraska, USA, with optically stimulated luminescence (OSL) ages and calibrated radiocarbon ages (data from Roberts et al., 2003 and Maat and Johnson, 1996). Also shown are absolute abundances of extralimital boreal and Cordilleran species of land snails (data from Rousseau and Kukla, 1994). Note that the section thickness as given by the latter authors differs slightly from that in Roberts et al. (2003); thus, depths of OSL ages in Peoria Loess are approximate.

Less-controversial methods have also been utilized in studying loess-derived paleosols, although not as commonly as magnetic susceptibility. In the Mississippi River valley of Illinois, soil morphology, particle size, and mineralogical and geochemical data show that paleosols differ in the amount of development and chemical weathering they have experienced (Grimley et al., 2003). For example, the Sangamon Geosol and an older paleosol, called the Yarmouth paleosol, are redder and more clay-rich than the Farmdale Geosol or the modern soil. Proxies for plagioclase depletion ($\text{Na}_2\text{O}/\text{TiO}_2$), apatite depletion ($\text{P}_2\text{O}_5/\text{TiO}_2$), and silicate mineral depletion in general ($\text{SiO}_2/\text{Al}_2\text{O}_3$) show that the Yarmouth paleosol has experienced more weathering than the Sangamon Geosol, which in turn has experienced more weathering than the Farmdale Geosol or modern soil (Figure 14). These data can be interpreted to mean that past interglacials were warmer and more humid than the present one, with enhanced chemical weathering in soils. An alternative interpretation is that past interglacials had a longer duration

than what the present one has experienced, or that past interglacials were warmer, more humid, and longer than the present.

Conclusion

Loess–paleosol sequences are one of the most important terrestrial records of Quaternary climate change. Loess is dominantly silt sized, windblown sediment, typically composed of quartz, feldspars, micas, carbonates, and clay minerals. These deposits usually blanket preexisting landscapes and can be centimeters to hundreds of meters thick. Loess is found over a large portion of the Earth's surface, in the central and northwestern United States, Alaska, Argentina, Europe, Russia, Central Asia, China, and New Zealand. It has distinct advantages over other Quaternary sediments in that it is a direct record of atmospheric circulation and can be dated directly, using luminescence methods. Many loess records

Figure 14 Stratigraphy and geochemistry of loess near Thebes, IL, Mississippi River valley, USA. Stratigraphy and $\text{Na}_2\text{O}/\text{TiO}_2$ data are from Grimley et al. (2003); other data, previously unpublished, are courtesy of D.A. Grimley, Illinois State Geological Survey.

span much or all of the Quaternary and thus represent a terrestrial analog to the deep-sea sediment record. In most regions, loess was deposited during glacial periods, and soils formed during interglacial periods. There are exceptions to this, however, and in some areas, such as China, neither loess deposition nor soil formation ever cease completely. Loess can be used to reconstruct paleowinds using spatial trends of thickness, particle size, and carbonate content. Although many paleoecological indicators are rare or absent in loess, shells of land snails are common and can be a powerful tool in reconstructing paleoclimate. Finally, paleosols in loess sequences have many characteristics that can be used to estimate past climates.

Acknowledgments

This review was supported by the US Geological Survey Earth Surface Dynamics Program and is a contribution to the 'Eolian History of North America' project. Dave Grimley kindly allowed use of unpublished data from his Thebes, Illinois loess section. I thank Lesleigh Andersen, Gary Clow, Scott Elias, Tom Judkins, Naomi Porat, and Helen Roberts for helpful comments on an earlier draft.

Central Asia can be regarded as one of the classical regions of loess distribution. During the Quaternary period, accumulation of wind-blown dust formed a widespread and thick loess cover at the piedmonts of the mountains in this region. Any traveler crossing Central Asia remembers the dust blown along desert and semidesert areas. The dust consists of clayey, silty, and fine sandy material derived from sandy deserts, from glacialfluvio/fluviol deposits of the river floodplains and from weathered and frost-shattered rock surfaces in high mountains where glaciers exist (Figures 1 and 2). The desert basins and the piedmonts of Central Asian mountains are arid to semiarid with the average annual air temperature of 10 °C or higher, and average annual precipitation between 200 and 600–800 mm, depending on the local climatic conditions. The plain regions, intramontane basins, and mountains to the north of the Hindu Kush are characterized by a dry, continental climate with moist, mild winters in the southern part and colder frosty winters in the north. Westerlies to the north of Hindu Kush provide a moist air-mass transfer during the winter–spring seasons, whereas a hot season occurs in the summer and early autumn period complemented by active eolian processes. Areas to the south of Hindu Kush and Himalayas belong to a warmer climatic belt, where Indian monsoon, carrying the moist air mass, occurs during the summer, while the winter and spring are a period of aridification when dust deflation is intensified.

Loess forms thick mantles which follow the shape of the present-day relief, smoothing it out or creating steep scarps and loess ‘cirques’ (Figures 3–5). Due to high porosity and permeability, water infiltration is pervasive in loess deposits, leading to widespread fluvial erosion, landsliding, collapsing, and redeposition (Figures 6 and 7). These processes create exposures for

studies of loess–paleosol strata on vertical loess walls, although trenches are usually prepared as well (Figure 8(a)–8(c)).

There are many hypotheses about the origin of loess. Loess experts such as Kriger (1965), Pécsi (1993), and Smalley et al. (2001) have systematically reviewed these hypotheses. One of the dominant models, the eolian theory of loess deposition, was proposed by the prominent nineteenth-century German scientist von Richthofen (1882), who had studied Chinese loess. A fundamental contribution to the eolian theory was made by Obruchev (1933) through his famous work on Central Asian loess from the end of the nineteenth to mid-twentieth century. A ‘proluvial’ hypothesis (deposition in the temporary water streams) of loess origin was proposed by Pavlov (1903), who studied loess and loess-like deposits in the Tashkent region. One of the independent hypotheses of loess formation was developed by Berg (1947), suggesting that loess results from *in situ* weathering and soil formation, called ‘soil-eluvial theory.’ This hypothesis was supported by some pedologists, such as Gerasimov (1976), who drew significant attention to pedogenic processes in loess formation; he considered that pedogenic hypothesis should not be in contradiction with the eolian idea of loess deposition. The idea of pedogenic formation and weathering was modified as a process called ‘loessification.’ A similar approach was elaborated by Minervin (1984), who used an *in situ* weathering model to explain the origin of collapsibility in loess strata by cryogenic processes. However, it should be emphasized that lack of cryogenic textures in Central Asian loesses does not allow acceptance of this model. The role of eolian sedimentation, explaining the uncompacted nature of loess and its formation in arid climatic zones such as Central Asia, was redeveloped by Kriger (1986). In addition, however, a polygenetic model of loess/loess-like formation should be mentioned, which results from a combination of different processes during deposition of loess and loess-like material (Mavlyanov, 1958). At present, the majority

of scientists accept that primary loess has an eolian origin, but most also recognize that in some areas, loess has been intensively reworked, and redeposited by slope processes and running water that results in what are called 'loess-like' deposits.

Central Asian deserts and piedmont plains have been subjected to deflation processes for many hundred thousands of years in the Quaternary. Vast amounts of silt material were formed from frost and thermal weathering as well as glacial grinding in high mountain areas that have glaciers or had them previously. Silt was washed out to become a part of the fluvial system in mountain valleys, piedmont fans, deserts and semi-deserts, extending over vast areas with an arid climate. Many millions of tons of dust from the arid deflation zone have been transported by dust storms and have accumulated on river terraces, plateaus, and mountain slopes (Figure 9). In the piedmonts of high mountain ranges, loess distribution is usually limited to elevations of 2000–2500 m, although fragments of thin loess cover occur even higher. For instance, in the Pamirs thin loess mantles can be encountered at an elevation of 4000 m, and in the northern Kunlun mountains, loess deposits are present at 4500 m.

The Central Asian loess region, to the north and west of the Pamirs, covers parts of several countries, including Uzbekistan, Kyrgyzstan, southern Kazakhstan, Tajikistan, Turkmenistan, and northern Afghanistan (Figure 10). The very arid territory of Xinjiang is east of the Pamirs. Loess is characteristic for the marginal parts of great Central Asian deserts such as the Takla Makan, Gobi, Karakumy, Kyzylkum, and Muyunkum (Figure 11). In the southern part of Central Asia, to the south of the Hindu Kush and Himalayas, loess is found in the intra-montane Kashmir valley and along the Siwalik foothills, to the north of the Thar desert, in the Punjab, the Peshawar basin, and the Potwar plateau. The sources of eolian dust for loess regions are the deflated sands and silts in deserts, fluvial and lacustrine deposits, and alluvial (proluvial) fans along

mountain fronts. In the southern part of Central Asia, to the south of the Hindu Kush, the thickness of loess cover is variable, from a few meters to 20–30 m. In the northern part of Central Asia, in key sections of the Tien Shan and Western Pamirs piedmonts, the loess mantle is thicker, particularly in southern Tajikistan and Uzbekistan, where it attains a thickness of 100–200 m.

Paleoclimatic fluctuations are manifested in loess strata as the alternation of soil and loess horizons. Many scientists assume that loess horizons in Central Asia were formed during the glacial/cold epochs, whereas formation of soils corresponded to interglacials or warm phases. According to another viewpoint, paleosols are associated with pluvial events correlated with glaciations, while loess horizons correspond to interglacials. As mentioned above, the low-latitude loesses of this arid zone lack cryogenic features, which is the reason they are called 'warm loess.' Nevertheless, apart from this characteristic, 'warm loess' is not really associated with interglacial periods. Loess-forming processes correlate with the increasing aridization and continental conditions associated with glacial periods, accompanied by considerable expansion of desert and desert-steppe landscapes in the lower piedmont zone. The available age control, data on paleosols, and paleontological and archaeological evidence indicate that regionally manifested soil-forming intervals are definitely related to interglacial events (An et al., 1991; Bronger and Heinkelé, 1989; Dodonov et al., 1999; Liu et al., 1985).

On the basis of analytical data and observation of loess in many localities of Central Asia, such as Tajikistan, Uzbekistan, and Kyrgyzstan, loess horizons can be described as well-sorted grayish-pale-yellow, homogeneous, porous clay-silt with a carbonate content up to 15–20%. Abundance of root-like calcite forms and amorphous concentrations of pelitic calcite are characteristic. In the north of Central Asia, the coarse silt fraction (0.05–0.01 mm) is dominant, ranging from 35 to 45% of the total and nearly 40% on average. There is a high content of the medium silt fraction (6–20 μ m, 30–40%) reported by Bronger et al. (1987) from Kashmir loess. A significant amount of medium silt suggests that the dispersed material was at least partially transported from remote territories located beyond the bounds of Kashmir valley. On the other hand, according to the data of Lodha et al. (1988), the average concentrations of elements such as K, Ti, and Fe in the loess–paleosol sequences of Kashmir correlate well with the rock mineralogy of the region, showing a dominantly local source of loess material. Particle size studies of Potwar loess in the Middle Soan valley (Rendell, 1988) reveal that the loess comprises 87–90% silt (silt-clay, according to Rendell) and 15–16% clay-size particles, and calcium carbonate contents in the range of 14–18%. The composition of loess in the Peshawar basin is very similar to this.

The regionally well-developed paleosols are gray, brown, and reddish brown in color and are decalcified to various degrees. They have an essentially clayey composition, the clay (<0.001 mm) content is up to 20–30%. Carbonate content varies from 0–3% in B horizons to 30–45% in underlying illuvial carbonate horizons. Most fossil soils are polygenetic, with interbedded zones of carbonate concretions. The genetic type of paleosols is generally recognized as the Serozem and Cinnamon types in the Russian soil classification (Egorov

et al., 1977), which correspond to the Haplic Calcisol and Castanozem types in the international soil classification (World Reference Base, 1998). A majority of the middle and late Pleistocene paleosols, in southern Tajikistan, are similar to the surface Holocene soils, formed at altitudes of ~1000–2200 m a.s.l. under a subtropical climate with a predominantly seasonal precipitation and vegetation characterized by broadleaf forest, or open forest-steppe, associated with grasses and shrubs. In the loess–paleosol sequences of Central Asia, the paleosols are frequently grouped into pedocomplexes (PC). They are defined as comprising two or more soils ('pedomembers'), which overlap each other or are separated by thin deposits within one member, and are overlain and underlain by greater thicknesses of loess separating different pedomembers/PC.

The loess-soil record in Central Asia suggests a long-term trend toward colder and drier conditions during the Quaternary. This trend is related to the uplift of Tibet, and the Tien Shan, Pamirs, and Himalayas mountain ranges. The uplift of mountains resulted in the extension of mountain glaciation and the appearance of a periglacial zone. Glacial and periglacial processes produced abundant silt material that was carried over by rivers to the piedmont plains, where it was deflated. Furthermore, the uplift of high mountain ranges created barriers for the transfer of moist air masses from the westerlies and the Indian monsoon. This resulted in a general desiccation of intramontane depressions and plateaus. Due to the enlargement of arid areas and more favorable conditions for accumulation of the fine-grained material, the broadening of loess regions in the middle and late Pleistocene resulted in the addition of the Kashmir valley, Peshawar basin, and Potwar plateau to the Central Asian loess province.

The loess–paleosol formations of Central Asia provide one of the most significant climatostratigraphic records on the continent. Paleomagnetic investigations and paleontological studies in Central Asia, especially in southern Tajikistan, have suggested an age of ~2.5 Ma for the oldest loess horizons. The most complete loess sequences in the Tajik Depression provide a detailed record of climate changes for the last 2.5 My. Over 40 paleosol horizons are interpreted to have formed during this period. A major shift toward a cooler and drier climate occurred at about 1–0.8 Ma, that corresponds to the interval between the Jaramillo Suchron and the Matuyama–Brunhes reversal. At this level, these changes are definitely marked by an increase in the thickness of loess horizons. The Matuyama–Brunhes reversal (~780 ka) is located in the loess horizon between the tenth and ninth PC, or at the base of PC9.

The oldest loess corresponds to the lower part of the Matuyama paleomagnetic interval, below the Olduvai Subchron. According to paleomagnetic markers used for estimating the duration of loess + paleosol pedosedimentary cycles, in the early Pleistocene, one loess–paleosol cycle lasted 35–50 ka; in the middle and late Pleistocene, each cycle had a duration of about 100 ka. These estimates reveal a correspondence with the general trend of paleoclimatic cyclicity reflected in the oxygen-isotope record for the past 2.5 Ma (Ruddiman et al., 1986; Shackleton, 1995).

Stratigraphic data obtained from loess sequences in the Kashmir valley, the Potwar plateau, and the Peshawar basin

Figure 12 Magnetic susceptibility records on loess–paleosol succession in Darai Kalon, southern Tajikistan, and its correlation with oxygen-isotope curve. Reproduced from Dodonov AE (2002) *Quaternary of Middle Asia: Stratigraphy, Correlation Paleography*, p. 250. Moscow: GEOS (in Russian); Figure 57, with permission from GEOS.

show that the initial stage of loess formation in southern Central Asia took place much later in comparison with northern regions, depending on the rate of aridification and sedimentary environment. In the Kashmir valley, a 20–30 m thick loess cover contains the last interglacial soil and below it there are at least four mostly polygenetic paleosol horizons corresponding to interglacials (Bronger et al., 1987). According to paleomagnetic measurements and thermoluminescence (TL) dating, their estimated age is not older than the middle part of the middle Pleistocene, although TL ages greater than ~100 ka have an uncertain reliability. Loess covers of the Potwar plateau and the Peshawar basin are thinner and apparently lack paleosols. Their TL age is mainly in the range of the late Pleistocene, with one earlier TL date of 170 ka (Rendell, 1988).

In the loess sequence of southern Tajikistan, the Brunhes paleomagnetic epoch includes nine PC. A similar sequence has been documented in the Tashkent region of Uzbekistan. The magnetic susceptibility record for this interval shows pronounced peaks corresponding to paleosols, which correlate reasonably well with those of the warm stages in the marine oxygen-isotope record (Figure 12). The geochronology for

the upper pedocomplex PC1 of Central Asia has been confirmed by TL dating (Frechen and Dodonov, 1998; Zhou et al., 1995). TL measurements yield ages in the range of 130–70 ka for PC1, establishing its correlation with stage 5 of the marine isotope record. Age markers such as PC1, corresponding to the last interglacial, and the position of Matuyama–Brunhes reversal at 780 ka have been used as the reference age levels for the general calibration of the Central Asian loess–paleosol succession as well as for correlation with oxygen-isotope stages. For the Brunhes Chron, the correlation of the loess–paleosol succession of Tajikistan and northern China as well as with the oxygen-isotope curve is illustrated in Figure 13.

Geochronology for the upper paleosols is very important for the reconstruction of early human evolution, because many Paleolithic sites have been discovered in pedocomplexes PC6, PC5, PC4, PC3, PC2, PC1 (Dodonov, 1995, 2002; Lazarenko and Ranov, 1977; Ranov and Schäfer, 2000). It has been established that PC6, PC5, PC4, and PC3, which contain stone artifacts of a pebble culture, span the time range between ~650 and ~300 ka. Younger pedocomplexes, PC2 and PC1, with stone implements of the middle

Figure 13 Stratigraphic correlation of Tajikistan summary loess–paleosol section with oxygen-isotope curve and summary loess–paleosol section of China. B/M – position of the Matuyama–Brunhes paleomagnetic reversal. Reproduced from Dodonov AE (2002) *Quaternary of Middle Asia: Stratigraphy, Correlation Paleography*, p. 250. Moscow: GEOS (in Russian); Figure 74, with permission from GEOS.

Paleolithic, are assumed to be in the range of ~250 to ~70 ka. The earliest stone artifacts have been found below the Matuyama–Brunhes paleomagnetic reversal in paleosols 11 and 12, which are estimated to be around 900 ka (Ranov and Dodonov, 2003). The most recent studies of loess–paleosol sequences demonstrate that the relatively wide expansion of Paleolithic people in the loess province of the Tien Shan and Pamirs piedmonts took place during the middle Pleistocene, whereas the earliest, stratigraphically proved, appearance of ancient man occurred in the late early Pleistocene.

It should be emphasized that numerous Paleolithic finds in the northern part of Central Asia have been recovered from well-developed paleosol horizons. The paleoclimatic conditions during the soil-forming epochs favored the habitation of ancient people. During loess-forming intervals, deteriorating climatic conditions, with severe winters and frequent dust storms, yielded abundant dust accumulation, and caused human migration away from zones of intensive loess formation to other areas. It is worth noting that ancient people returned to the same loess regions during later periods of soil formation. According to paleoenvironmental reconstructions, the archaeological sites in loess sections were located at river

banks, on slopes along river valleys and on river divides. Ancient people used pebbles from alluvial gravels for making tools, and water from the springs in gorges. The loess watersheds were a good place for hunting. The Paleolithic artifacts are mostly found in Bt horizons of the interglacial PC and are attributed to climatic optima. The habitats of hominids were probably forest-steppe and steppe, based on paleoclimatic reconstructions. Notably, the paleosol-related pebble tools do not permit the identification of distinct cultural horizons. The stone artifacts are generally dispersed throughout the paleosol profile. This situation may be accounted for by the accumulation of dust material during the soil-forming epochs, that is, it corresponds to a syndepositional model of soil development. Another factor in the vertical distribution of artifacts in paleosols is the recurrent occupation of ancient people at the same site. All these factors contributed to the significant depth range of artifacts and is a very characteristic pattern for loess Paleolithic sites in Central Asia.

In the southern part of the Central Asian loess region, the presence of the Late Soan stone industry in the loess cover on the Soan river terrace (T_2), 30–40 m height, as well as in the basal alluvial gravels has been reported by de Terra and Paterson

(1939) and supported by Movius (1944). It has been inferred from the geoarchaeological context in the Soan valley that occupation by the Soan people covered both the pluvial and interpluvial phases. Therefore, in this region, Paleolithic humans likely witnessed dust storms during the arid periods.

The pollen spectra obtained from loess–paleosol sequences have a complex, mixed composition, which does not usually show distinct differences between the loess horizons and paleosols. Nevertheless, the palynological data from one of the reference sections, Darai Kalon in southern Tajikistan, demonstrate a rather good agreement with the pedological features. Arboreal pollen dominates in the well-developed, typical and leached Cinnamon Soils of PC4, PC3, PC2, and PC1. The lower paleosol members in these pedocomplexes are the most well developed and show soil formation under a more humid climate, whereas the upper soils are less developed and reflect drier environments. Pollen assemblages of PC1 correlate well with the paleopedological data, demonstrating the upward decrease of arboreal pollen and increase of grasses. The upper paleosol of PC1, assigned to the Serozem soil type, is characterized by a predominance of herb and shrub pollen.

The mammalian fossils contained in the loess–paleosol sequences and associated sediments reveal the regional Quaternary evolutionary history of mammals and provide useful biostratigraphic data, as well as reflecting the ecological conditions in loess regions of Central Asia. The paleoecological study of the late Pliocene–early Pleistocene fauna in the northern Central Asian localities, together with palynological data, shows the mosaic-like structure of paleolandscape and distinct altitudinal zonation. For instance, at the Kuruksay locality (~2.4–2.0 Ma), in southern Tajikistan, the inhabitants of dry, open landscapes such as hyenas (*Pachycrocuta*, *Chasmaporthetes*), antelopes (*Proteryx*, *Damalops*), camels, and cheetahs are characteristic, while the presence of bears, cervids, and primates (*Paradolichopithecus*) suggests a landscape with mixed shrub and bush areas and forest belt in the high piedmont (Sotnikova et al., 1997). At that time, loess had just started to be deposited, covering the watersheds and slopes, and reworked by pedogenic processes, resulting in the formation of pedosediment. The mammalian fauna from the next interval, at the end of the early Pleistocene, as demonstrated in the thoroughly studied Lakhuti locality of southern Tajikistan, yielded an open steppe fauna, such as hyenas, camels, and horse, as well as cervids (*Sinomegaceros* and *Praemegaceros*) connected with woodland patches. Among small mammals, inhabitants of the arid zone, *Ellobius*, *Meriones*, and *Cricetulus*, were also present. Carnivores such as the small wolf, *Xenocyon*, the giant hyena *Pachycrocuta brevirostris*, and felids were also common elements (Sotnikova et al., 1997). It is worth noting that loess accumulation significantly increased from the beginning of the middle Pleistocene. During the periods of loess sedimentation along the Siwalik foothills, there were dry plains and plateaus inhabited by horse, bison, camel, and wolf.

The geochronological data and paleomagnetic markers are accepted as a basis for evaluating the mean loess sedimentation rates during the Quaternary, using the thickness of loess–paleosol series. An approximation of loess sedimentation rates for key loess sections in southern Tajikistan results in a trend of loess accumulation in a range from 0.05 to 0.16 mm year⁻¹

Figure 14 Variations in the thickness of loess–paleosol strata, marked by wide columns, and mean sedimentation rate, narrow columns, during the last 2.5 Ma. Age boundaries in the loess reference sections of southern Tajikistan, Chashmanigar, Karamaidan, Khonako, Darai Kalon, Kairubak, Lakhuti, and Karatau, dated by paleomagnetic and thermoluminescence methods have been used for estimation of loess sedimentation rate. Reproduced from Dodonov AE (2002) *Quaternary of Middle Asia: Stratigraphy, Correlation Paleogeography*, p. 250. Moscow: GEOS (in Russia); Figure 75, with permission from GEOS.

during the last 2.5 Ma (Figure 14). This estimation of rates does not take into account the duration of soil formation, when dust sedimentation was steadily reduced. The mean sedimentation rate of loess itself, excluding the paleosols, attained an average rate of 0.2–0.3 mm year⁻¹ and even up to 0.4 mm year⁻¹ (Figure 15). On the basis of TL ages, the sedimentation rate varied from 0.08 to 0.27 mm year⁻¹ in the Potwar plateau and the Peshawar basin for the late Pleistocene (Rendell, 1988). It should be noted that proportional changes of sedimentation rates have been calculated for different loess provinces, for example, southern Tajikistan and Loess Plateau of China, as illustrated in Figure 14. This demonstrates the general regularities in development of eolian processes in different regions of Asia, affected by uniform paleoclimatic changes.

In the current conditions of Central Asia, to the north of Hindu Kush, the summer–autumn period is favorable for dust storms, owing to minimal precipitation and intense drying of soil covered by scarce vegetation. The number of dust-storm days per year ranges from five in the Pamir–Alai and Tien Shan valleys to 50 and more in Turkmenistan, Uzbekistan, and other areas of sandy grounds not covered by vegetation (Figure 16). In the Takla Makan desert, dust storms occur on more than 30 days per year (Pye and Zhou, 1989). Today, intense deflation and dust accumulation are observed in the high mountain valleys in the glacial zones of the Eastern Pamirs and the Central Tien Shan, at the altitude of 3500–4000 m a.s.l. To the south of the Hindu Kush and Himalayas, the Central Asian loess province is located within the limits of the Indian monsoon, where the bulk of precipitation occurs mainly in the second half of the summer and the early autumn. Here, intense eolian dust falls during the dry season, which lasts up to 9 months. More than 30 dust storms per year occur in northern Pakistan.

Figure 15 Loess sedimentation rate for the last 1 Ma excluding the time span of paleosol formation. The data on the loess reference sections Darai Kalon (after Dodonov) and Tagijar (after Dodonov and Haesaerts) in southern Tajikistan, and the Huangling section in northern China (after Haesaerts). Figure 16 The annual frequency of dust storms in Central Asia to the north of the Hindu Kush. Reproduced from Dodonov AE, Shackleton N, Zhou LP, Lomov SP, and Finaev AF (1999) *Quaternary loess-paleosol stratigraphy of Central Asia: Geochronology, correlation and evolution of paleoenvironments. Stratigraphy and Geological Correlation* 7(6): 66–80.

Loess areas of Central Asia are highly populated regions, with high intensity of agriculture and industrial development. Thus, these areas are very sensitive to geological changes and geotechnical impact. One of the problems regarding the exploitation of loess-mantled landscapes is collapsibility. The studies carried out in the former Soviet Central Asia indicate that in the areas with thick loess cover, the thickness of the collapsible zone attains a depth of 30–40 m from the surface. Collapse properties are explained by the lack of compact quality of loess as a result of cementation of loosely deposited sediments under arid climate. This characteristic, called Denisov's principle, was considered in depth by Kriger (1965, 1986) and his collaborators. The model is in good agreement with the concepts of the eolian genesis of Central Asian loess. Another problem connected with changing of the water balance over vast loess areas is the rational supply of water resources in Central Asia. Areas covered by permeable loess-derived soils are often exposed to underflooding. The highly populated cities of Central Asia such as Tashkent, Dushanbe, and others suffer greatly from the underflooding processes, creating collapsibility and settlement of soil foundations, deformation of buildings, etc. Many geological processes, which are active in Central Asian loess regions, such as erosion, suffusion, collapsing, landsliding, and underflooding, are intensified in connection with human activities. Another very serious factor in Central Asia is seismic activity. Loess mantles are highly susceptible to seismic movements. In loess areas, seismic subsidence, landslides, and slope earthflow are characteristic results of earthquakes. We are now in an epoch of construction and very progressive development of Central Asian countries. Industrial and civil buildings, highways, hydrotechnical and irrigation systems are gradually modifying and removing the very sensitive loess cover.

Introduction

Loess consists largely of silt-size mineral grains that have been deposited by wind to form homogeneous nonstratified sediment of local to regional extent. Widespread loess is now found mainly in temperate latitudes of central Asia, northwestern and central USA, central Europe, and Argentina. Loess also is present in high northern latitudes, including northern Russia and interior Alaska, and reportedly occurs in part of tropical South America. Most deposits are of Pleistocene age and typically formed under arid to semiarid conditions. Major loess regions lie downwind from source areas that include deserts, periglacial zones, and the floodplains of melt-water streams that drain large piedmont glaciers and ice sheets. Loess typically forms a blanket across the landscape. Where thin it mirrors the underlying topography, but where thick (≥ 100 m) it may form a constructional surface that obscures underlying bedrock terrain. Because it consists of fine-grained, little-weathered minerals, in humid-to-semihumid regions loess generates rich soils that support crops to feed millions of people.

Loess in China

Central China is one of the world's most extensive and important loess regions. The loess caps a broad dissected plateau, the Loess Plateau, which lies largely within the great northward bend of the Yellow River (Huang He) as it emerges from the Tibetan Plateau near Lanzhou (Figure 1). It forms distinctive landscapes, to which the Chinese have given an elaborate series of specific names (e.g., yuan (high, flat tableland), ta (rounded hills), liang (ridges)). The flat-topped yuan are extensively farmed, as are nearly all gentle slopes in the loess region. Deep valleys cut into the coherent loess deposits often have steep cliffs in which can be seen alternating bands of yellowish loess and reddish-brown buried soils (paleosols) that form a record of changing climate conditions through time (Figure 2).

Monsoon Climate of Eastern Asia

The history of Chinese loess deposition is closely linked to the East Asian monsoon climate system (Figure 3). The monsoon is driven by differential heating of the land and adjacent ocean. During the annual transition from winter to summer, northern hemisphere insolation slowly increases. The land warms more rapidly than the ocean, thereby strengthening the temperature contrast between the warm Asian continent and the cooler Pacific Ocean. The resulting pressure gradient between ocean and land produces a steady flow of moist marine air onto the continent during the summer and early autumn. Interaction along the monsoon front between this warm, moist Pacific air and cooler, drier continental air produces a belt of heavy rain

that migrates inland. With the approach of winter, insolation declines, summer monsoon conditions weaken, and cold, dry northwesterly air flows southeastward from a large region of high pressure that expands over north-central Asia. As the winter monsoon strengthens, dust is deflated from arid source regions and is spread across China's loess region and beyond across the North Pacific Ocean. Loess accumulation is greatest during winter and spring when the winter monsoon is strongest, and soils mainly develop under moist, warm summer monsoon climate.

Accretionary Paleosols

Paleosols found in most continental loess sequences represent times when dust sedimentation ceased and soil-forming processes operated on stable land surfaces. In monsoonal China, however, dust deposition is essentially continuous, although variable in rate. Soil formation also takes place continuously as dust accumulates, but at variable rates and intensities. The resulting soils are accretionary soils; when buried by younger loess deposits they become accretionary paleosols. Such paleosols do not record breaks in the stratigraphic record. Instead, they represent intervals when soil-forming processes intensified while dust accumulation proceeded at a slow rate.

Loess/Paleosol Stratigraphy

Stratigraphic studies of the loess and paleosol sequence in the Loess Plateau have used lithology (e.g., color, relative thickness, grain size, and mineralogy) and soil characteristics, as well as magnetic properties as primary criteria for classification and correlation. Magnetic susceptibility (SUS) has proved especially useful in this regard (Figure 4). The primary susceptibility signal originates from *in situ* production of fine-grained magnetic particles (maghemite) by soil bacteria. SUS values are highest for warm, mild interglacial conditions that promote soil formation, and lowest for glacial times when cold, dry conditions prevailed.

The standard stratigraphic succession has been divided into primary numbered loess and paleosol couplets and secondary units within some loess or paleosol units (Figure 5). The letter L is used to designate loess units and S for paleosols. Successive units are given higher numbers with increasing age. Some 32 primary couplets have been identified in a classic loess succession near Baoji in the central loess region, the oldest units being designated L32 and S32 (Figure 6). Particular attention has been given to deposits of the last interglacial/glacial cycle (S1 through L1) and the thin overlying late Holocene ('Potou') loess and early-to-middle Holocene paleosol (S0) (Figure 5). The L1 loess, also called Malan Loess, includes two primary loess units (L1LL1 and L1LL2) and an intervening weak soil or

Figure 1 Map of the Loess Plateau and adjacent sandy deserts in central China.

soil complex (L1SS1). The S1 paleosol complex below the Malan Loess consists of three soils separated by two loess units.

Chronology of Loess and Paleosol Units

Ages for eolian strata have been obtained based on several complementary methods:

- radiocarbon dating of the middle and upper Malan Loess (i.e., the last ~50 000 years);
- luminescence dating of the younger part of the classic loess sequence (the last ~200 000 years);
- cosmogenic-isotope dating using the beryllium-10 (^{10}Be) isotope;
- paleomagnetic dating based on interpolation between polarity reversals of known age assuming (i) a nearly constant long-term accumulation rate of dust and weighting the thickness of a layer by its SUS, or (ii) using the concentration of magnetic minerals as an approximation of geologic time;
- grain-size data (i) 'orbitally tuned' to the marine oxygen-isotope record obtained by the SPECMAP (Mapping Spectral Variability in Global Climate Project), following correlation of loess and paleosol boundaries with isotope-event boundaries; (ii) correlated with the SPECMAP record to derive a sedimentation rate for each unit, its duration (ratio of layer thickness to sedimentation rate), and its age (by summing the duration of deposition of all overlying units), or (iii) using the coarse silt ($>40\ \mu\text{m}$) fraction, or the median diameter of the chemically isolated quartz fraction as a proxy for dust deposition rate, ages being assigned based on an accumulation-rate model linked to the SPECMAP record. In the latter approach, the estimated error of ages over the last glacial-interglacial cycle (the last ~130 000 years) is about 1000–3000 years.

Figure 2 A steep stratigraphic section at Luochuan on the central Loess Plateau shows alternating yellowish-brown loess and reddish-brown paleosols (SCP photograph 94-310).

Comparison with the Marine Isotope Record

The basic stratigraphy of the classic Chinese loess succession is strikingly similar to variations in the marine oxygen-isotope stages (MIS; **Figure 6**). Paleosols correlate with odd-numbered isotope stages (interglaciations) and loess units with even-numbered stages (glaciations). The pattern of variations in SUS of the loess and paleosol succession is essentially identical to and correlates with isotope variations in the marine record over at least the last 2.5 My. Both vary in phase with Milankovitch Earth-orbital cycles, implying that the monsoon climate of east-central China has fluctuated synchronously with variations in solar radiation reaching the Earth's surface. Clearly discernible in the loess record is a ~40 000-year (obliquity) cycle that is dominant prior to about 800 000 years ago. It was replaced by a dominant 100 000-year (eccentricity) cycle that extends to the present and also is a major feature of the marine isotope record.

Variations in Grain Size and Thickness

The loess reaches a thickness of 300–400 m in the central and western part of the Loess Plateau, and thins progressively toward the southeast. Very few exposed sections include more than the upper half of the loess sequence, and so the regional pattern of thickness of the oldest units cannot be determined with confidence. Instead, the thickness of the Malan Loess

Figure 3 Map of eastern Asia showing seasonal conditions of the East Asian monsoon system. (a) Mean January sea-level pressure field (hPa) generates a southward flow of cold, dry air (arrows) across China's loess region from a zone of high pressure centered over southern Siberia. (b) During July, a reversal of wind flow brings warm, moist air inland across the loess region from the south China Sea (after Xiao et al., 1995, Figure 1).

(L2–L4), which is easily measured at numerous sites, has been used to determine regional thickness variations (Figure 7). This unit is thickest (≥ 30 m) in a belt that extends northeastward from Lanzhou to the southern margin of the Mu Us Desert. Isopachs (lines of equal thickness) decrease in magnitude southeastward toward the junction of the Wei River and Yellow River where the thickness averages about 5 m.

Measurements of the median diameter of loess at the ground surface in transects across the Loess Plateau demonstrate a southeastward decrease in particle size from ~ 80 μm near the desert margin to 20 μm at the southeastern limit of the plateau. Comparable measurements for the Malan and older

thick loess units are difficult to assess, for their grain size varies not only horizontally but vertically as well (a response to changing climate). Therefore, unless the same (thin) stratigraphic level within a loess unit can be sampled at each site, a difficult task due to dating uncertainties, systematic regional trends in grain size are difficult to define accurately.

Potential Upwind Source Regions

The exponential southeastward decrease in thickness of Malan Loess and a decrease in mean particle size of surface loess in

Figure 4 Magnetic susceptibility (SUS) profiles through loess and paleosols spanning the last 130 000 years at three sites on the western (Beiyuan), central (Heimugou), and southeastern (Baimapo) Loess Plateau. The chronology is based on luminescence ages. Reproduced from [An Z, Kukla G, Porter SC, and Xiao J \(1991\)](#) Magnetic susceptibility evidence of monsoon variation on the Loess Plateau of central China during the last 130,000 years. *Quaternary Research* 36: 29–36, Figure 2.

that direction imply that the dust was derived from a source or sources lying northwest of the Loess Plateau. Sandy deserts have long been considered potential sources. Mongolia's Gobi Desert, an oft-cited possible source, is both arid and a source of modern dust storms, some of which have crossed the Loess Plateau. Other likely source regions are desert basins in China west and north of the Loess Plateau (e.g., Mu Us, Tengger, and Badain Jaren deserts; [Figure 7](#)). The vast Takla Makan sandy desert in the Tarim Basin, the dry surface of which is covered by extensive dune fields, playas, and large marginal alluvial fans, is also a potential source ([Figure 8](#)). Glacial silt transported by meltwater streams from surrounding high mountains to alluvial fans and playa surfaces in these basins during successive glacial ages could be lofted by strong westerly windstorms and carried in the direction of the loess region. Mineralogic, isotopic, and geochemical studies in

which silt from these deserts is compared with loess on the Loess Plateau support the likelihood of multiple loess source areas.

Downwind Transport and Deposition

Chinese loess thins rapidly beyond the Loess Plateau, and farther downwind the fine-silt fraction is detectable in sediment cores from Lake Biwa, Japan, as well as in deep-sea sediments across the North Pacific Ocean ([Figure 9](#)). In the Hawaiian Islands, Chinese dust has been identified from its fine-grained quartz component, for quartz does not occur naturally on these mid-ocean islands. Its presence in Greenland ice means that the fine dust must also have been spread across North America as well, but its very fine grain size, extreme thinness and

Figure 5 Stratigraphic subdivision and nomenclature of loess and paleosols on the Loess Plateau that span the last ~130 000 years, and their correlation with the standard marine oxygen-isotope stages and substages. Subdivisions are made on the basis of physical, chemical, and biological properties. Reproduced from Porter SC (2001) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 2.

erodibility, and nondistinctive mineralogy on the continent make its recognition highly unlikely.

Rates of Dust Influx

It is apparent from the loess and paleosol stratigraphy that the rate of dust accumulation has varied through time: glacial-age loess units are thick compared to interglacial accretionary paleosols. Quantitative estimates of dust influx rates can be obtained from well-dated sections, but these are rare. The section at Luochuan in the central Loess Plateau is among the best studied and most carefully dated. Based on a dust-flux model, the average dust flux during the last 120 000 years was $0.13 \pm 0.02 \text{ mm year}^{-1}$ (Figure 10). During the height of the last glaciation (i.e., loess L1LL1), the average full-glacial rate was $0.30\text{--}0.35 \text{ mm year}^{-1}$, but during the last interglaciation (paleosol S1) it was $<0.10 \text{ mm year}^{-1}$. Along the western margin of the plateau and along the Yellow River near Zhengzhou, loess of the last glaciation is far thicker and influx rates locally were as high as 1 mm year^{-1} .

In the North Pacific Ocean, far downwind from the Loess Plateau, the rate of dustfall has been calculated from deep-sea sediments, the mineral content of which is predominantly air-fall dust from western China.

Figure 6 Correlation of the loess-paleosol succession on the Loess Plateau spanning the last 2.5 My with the marine oxygen-isotope record and the paleomagnetic reversal chronology. Reproduced from Porter SC (2001) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 1.

Late Quaternary Loess/Paleosol Record

The SUS of loess has been used as a proxy for summer monsoon strength, for it is regarded as being strongly related to seasonal precipitation and temperature. The intensity of SUS at the land surface diminishes northwestward across the Loess Plateau, reflecting a decrease in summer monsoon strength and in related soil-forming activity (enhanced production of maghemite) in that direction (Figure 4). In most loess profiles that span late Quaternary time, SUS closely resembles the standard MIS pattern, which leads to the conclusion that both records reflect a response of climate to changing Earth-orbital (i.e., Milankovitch) conditions. SUS was high during the present (Holocene) interglaciation (MIS 1) and the last interglaciation (MIS 5), but low during coldest parts of the last glaciation (MIS 2 and 4; Figure 11). In other words, low SUS is consistent with cold, dry glacial conditions while high values correlate with warm, moist interglacial conditions. Intermediate values characterize MIS 3.

Unlike the SUS signal, loess particle size displays high-frequency, high-amplitude variations through time (Figure 11). Intervals marked by coarse-grained loess are inferred to reflect climates in which strong winter monsoon conditions are dominant and strong winds were able to transport larger particles and greater amounts of dust. They also likely reflect increased

Figure 7 Map of Chinese Loess Plateau and adjacent sandy deserts showing regional variation in thickness (in m) of Malan Loess (L1). A logarithmic decrease in thickness across the plateau suggests that dust-bearing winds flowed southeastward from dust source areas to the northwest. Reproduced from Porter SC (2001) Chinese loess record of monsoon climate during the last glacial–interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 3.

Figure 8 Satellite image of the Takla Makan Desert in the Tarim Basin showing extent of dune sands on desert floor, basin-margin alluvial fans, and glacierized mountain ranges bordering the tectonic depression. Fine-grained meltwater sediments are transported to playas on the desert floor from which they are entrained by winds that carry them to the loess region downwind to the east (NASA image A2001300).

frequency and intensity of dust storms that followed surface storm tracks moving across dust source areas. Despite the high-frequency variability in the grain-size record, if the data are smoothed, the resulting curve rather closely resembles the SUS record. Not surprisingly, Late Pleistocene dust flux on the central Loess Plateau has a pattern that resembles both SUS and the grain-size data (Figure 9).

Glacial–Interglacial Dust/Paleosol Model

A simplified model showing the relationship between changes in summer monsoon climate, dust accumulation, and soil formation illustrates how the loess/paleosol stratigraphy develops (Figure 12). During peak cold, dry phases (stades) of glaciations, the average rate of dust accumulation is high and the rate of soil development is low. Warm, moist interglacial times are characterized by a threefold or greater reduction in dust influx and by intensified soil formation. Interstades, which are warmer and moister intervals within glaciations, show intermediate values between these more extreme conditions. During interglaciations, dust accumulation proceeds at a much slower rate, while during glaciations the intensity of soil development is greatly reduced.

High-Frequency Variations in the Dust Record

The prominent grain-size peaks that appear in loess records at frequent intervals record short-term (millennial-scale) changes of climate that are not detectable in the SUS data. A record of variation in the size of wind-transported quartz grains in the central Loess Plateau (Figure 11) displays prominent peaks at about 67 500, 50 500, 43 500, 33 500, 26 000, 21 500, and 15 000 years ago that must be related to intervals of pronounced strengthening of the winter monsoon. These also were times when large-scale ice rafting occurred in the North Atlantic Ocean related to partial disintegration of bordering continental ice sheets and the generation of exceptionally cold surface ocean waters in this region. Known as Heinrich Events, the ice-rafting episodes are linked to changes in climate in the North Atlantic and in many other parts of the world.

Figure 9 Variations in dust flux during the last ~150,000 years along a transect from the Loess Plateau to Japan (Xiao et al., 1997), the North Pacific Ocean (Hovan et al., 1991), and the Greenland Ice Sheet (Greenland Ice-Core Project Members, 1993). Intervals of greatest and least dust flux are similar among these records, but obvious differences in detail likely reflect differences in the parameters that were measured, the spacing of samples, and chronological uncertainties. Reproduced from Porter SC (2001) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 9.

Figure 10 Dust-flux values for the last glacial-interglacial cycle at the Luochuan section in the central Loess Plateau. The mean value is 0.13 ± 0.02 mm year⁻¹. During deposition of loess L1LL1, during full-glacial time (=MIS 2). The rate averaged 0.30–0.35 mm year⁻¹ and during the last interglaciation when the S1 paleosol formed (=MIS 5), the rate fell to <0.10 mm year⁻¹. Reproduced from Porter SC (2001) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 6.

The recognition of apparently correlative climatic events in the Chinese loess record in the form of increased dust-fall activity is intriguing, and a common cause of the implied climate linkage deserves further study. A similar high-frequency variation in grain size, although of lower amplitude, has been detected in loess records that span the last interglaciation (MIS 5). Their ages compare closely with surface cooling events detected in North Atlantic deep-sea sediments.

The 'Red Clay' and the Onset of Loess Formation

Throughout the Loess Plateau, the primary Quaternary loess and paleosol section rests on reddish silt and clay. This unit, known informally as the 'Red Clay,' has long attracted attention because of its rich content of Tertiary mammal fossils. Paleomagnetic measurements indicate that it is older than 2.5 My (Figure 13). Recent investigations have shown that the Red Clay consists of alternating layers of reddish eolian silts and carbonate-rich dark-reddish paleosols similar in character to those in the overlying loess/paleosol section. Sedimentary, geochemical, and mineralogical studies confirm that the formation is mainly loess. At the Lingtai section in the middle of the Loess Plateau, the entire eolian section is nearly 300 m thick, with the Red Clay component measuring 125 m. The upper part of the Red Clay is strongly weathered, as indicated by its intense reddish color and the structure of its soils. A cyclic pattern is apparent, with more than 100 discrete couplets of weathered loess and accretionary soil having been identified. The average accumulation rate of the Red Clay section was about half of that of the overlying Quaternary section.

It is now apparent that accumulation of eolian dust on the Loess Plateau was not restricted to the last 2.5 My, as previously thought. At several sites in the middle of the Loess Plateau, the base of the Red Clay dates back 6.5–7.2 My – well into the late Miocene. Paleomagnetically dated eolian sediments in thick sections near Lanzhou extend back 22 My, meaning that the onset of loess accumulation and of the monsoon climate likely dates back to the early Miocene. A progressive increase in summer monsoon strength and sedimentation rate over this long time interval has been attributed to progressive uplift of the Tibetan Plateau and the aridification of central Asia, which

Figure 11 SUS and grain-size profiles through loess and paleosols of the last glacial-interglacial cycle. These parameters serve as climate proxies for summer and winter monsoon variations, respectively. The latter record shows higher variability at the millennial timescale, but the smoothed curve (bold line) bears a general similarity to the curve of SUS. Peaks in grain size occur at times of extensive iceberg discharge into the North Atlantic Ocean (Heinrich events), which apparently had a strong effect on global climate. Reproduced from [Porter SC \(2001\)](#) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 7.

Figure 12 Inferred relationship between changing monsoon climate and the formation of loess and paleosol sequences in the loess region of China. During cold, dry glaciations, dust transport and deposition reached a maximum, while during interglaciations soil formation occurred under warm, moist conditions. Reproduced from [Porter SC \(2001\)](#) Chinese loess record of monsoon climate during the last glacial-interglacial cycle. *Earth Science Reviews* 54: 115–128, Figure 8.

Figure 13 Paleomagnetic polarity, SUS, and grain-size record of the Lingtai site on the Loess Plateau. The 'classic' loess section extends back about 2.7 Ma, but loess deposition and soil formation also characterized the Red Clay, which in this profile extends back more than 7 Ma, through the Pliocene and into the late Miocene. Reproduced from [An ZS \(2000\)](#) The history and variability of the East Asian paleomonsoon climate. *Quaternary Science Reviews* 19: 171–187, Figure 4.

were primary factors leading to the development of the East Asian monsoon system. SUS values show a long-term overall increase between 7.0 and 2.7 Ma.

Erosion of Loess and Loss of Topsoil

China has one of the world's highest rates of soil erosion, which affects 19% of the country's land area. On the Loess Plateau, where the soil loss is particularly devastating, 70% of the land is subjected to erosion. The unconsolidated to semi-consolidated nature of loess makes it highly susceptible to

erosive processes, and vast amounts of loess and soils are eroded from the landscape annually. Gully erosion on steep hillslopes is widespread and constitutes a primary source of fine sediment entering tributary streams. Each year the Yellow River erodes some $16\text{--}18.8 \times 10^8$ tons of loess and topsoil, which imparts a dark yellowish-brown color to the turbid water. The sediment discharge of the Yangtze River exceeds that of the world's two largest rivers, the Nile and Amazon. Between 1949 and 1990, sedimentation along river channels reduced their navigable length by more than 50%. Large quantities of sediment are deposited in reservoirs behind artificial dams along the main river courses and their tributaries. Dam

construction is motivated by the need for flood control and hydroelectric power, but rapid deposition of fine-grained sediment in reservoirs results in progressive reduction in their storage capacity and effective lifespan. The removal of topsoil by fluvial erosion in the loess region is a serious problem because this is prime agricultural land that supports many tens of millions of people.

Environmental Hazards in the Loess Region

A dense human population, intensive agriculture, and natural geologic processes operating in loess-covered terrain can lead to environmental hazards that impact thousands to millions of people.

Landslides

Under normal conditions, loess is stable and can stand as abrupt steep cliffs along valley sides. However, it is very susceptible to landsliding if stability is perturbed. Although the loess is permeable, paleosols are less so. Downward and lateral movement of groundwater along the top of less-permeable paleosols can destabilize the overlying loess and lead to slope failure. The contact between basal Quaternary loess and the less-permeable Red Clay is also a locus of groundwater movement that can lead to massive failure of the overlying loess.

The southern Loess Plateau is susceptible to large earthquakes that can generate extensive slope failures. A most remarkable example is the great Huaxian earthquake of 1556 that occurred along the southern margin of the Wei He graben east of Xi'an. The huge earthquake is estimated to have been of magnitude 8.0 and it generated many landslides. The human casualty toll of this quake was more than 800 000 people. Many of the fatalities likely were caused not only by landslides along steep loess slopes but also by collapse of cave houses excavated in the loess, which are and were numerous in this region (Figure 14).

Figure 14 Cave house excavated in loess. The interior extends back about 10 m, the floor being cut across a reddish paleosol and the walls in the overlying loess unit. Collapse of such dwellings in the loess region likely contributed to the high death toll associated with the great Huaxian earthquake of 1556 (SCP photo 92-441).

Endemic Diseases of the Loess Region

Several important endemic diseases affect the inhabitants of China's loess region. Keshan disease, a frequently fatal impairment of the cardiac muscles, is prevalent in rural villages lying within the humid-to-arid transition zone that crosses the central Loess Plateau. Recent studies conclude that the disease is related to water, soil, and geology. It is largely restricted to hilly regions, rather than to flat yuan terrain or river floodplains. The disease always occurs where strong leaching has removed important nutrients from soils, especially selenium. Adding this element to table salt appears to control this disease.

Kaschin-Beck disease has a similar distribution and causes painful changes in joints and bones. Studies have shown that it, too, is related to selenium deficiency in the diet.

Endemic fluorosis is caused by fluorine excess (poisoning) that leads to aching bones, kidney stones, deformed limbs, and eventual paralysis. Fluorine can reach high concentrations in the loess, meaning that persons living in the loess region can be easily susceptible to this disease. Prevention and successful cures involve extraction of drinking water from deep wells, and water treatment.

Other diseases also apparently are specifically related to widespread surficial loess. For example, Keding disease and goiter are dysfunctions of the thyroid gland related to lack of iodine and are widespread in the loess region where iodine content of groundwater is very low; prevention and treatment involve adding iodine to table salt. Cancer of the esophagus, the third most prevalent cancer in China, is especially serious in the southeastern Loess Plateau. Although the mortality associated with this disease correlates closely with loess particle size, the specific cause of the relationship is still unknown.

Introduction

The loess of Europe makes up the western end of the most extensive and voluminous loess belt on Earth that stretches some 10 000 km eastward to China's Pacific coast. Owing to its eolian origin, loess occurs on the landscape as relatively thin drapes, a few meters thick, on mountain foot slopes and on river terraces. Loess from five to several tens of meters in thickness is mainly found in basins, major river valleys, and on plateaus and extensive plains, as shown in the influential map of loess distribution in Europe published by [Grahmann \(1932\)](#). European loess generally lies outside the limits of the last Fennoscandian and Alpine glaciations ([Figure 1](#)), with extensive mantles in southern Russia, northern Ukraine and Belarus in the east, northern France and southern England in the west, and the Po Basin of northern Italy in the south. Although loess is described as an eolian sediment in Chinese texts more than 2 ka old, the process link between dust transport and loess deposits was not widely accepted in Europe until the German scientist [Richtofen](#) published his work on the Chinese loess, which he considered very similar to the loess of eastern Europe ([Pye, 1995; von Richtofen, 1882](#)). For a definition of loess, see [Pye \(1984\)](#).

The discovery and first scientific description of European loess is attributed to Karl Caesar von Leonhard, who, in approximately 1820, noted pale yellow, unstratified sediment, containing snail shells and fossil root channels, in the Neckar River Valley east of Heidelberg, Germany. He called it 'loess,' a local word used to indicate a yellow lime-rich soil ([Smalley et al., 2001](#)). A number of years later, von Leonhard showed the loess outcrop to Charles Lyell who was so impressed that he included substantial text on loess in his 'Principles of Geology' (1833), which certainly led to increasing recognition of loess by the world's geologists.

Loess of Europe: The Material

Mineralogy of European Loess

The most common mineral in most European loess is quartz (~40–80%), the principal ancillary minerals being the feldspars (predominantly K-feldspar), carbonates, and clay minerals. Exceptions include some Carpathian Basin loess, in which phyllosilicates are the dominant mineral group (up to 34%). Heavy minerals, although constituting only a small percentage (<5%) by weight, have proved useful as indicators of provenance and degree of pedogenesis in both loess and paleosol units ([Maruszczak and Wilgat, 1995](#)). While the calcite–dolomite ratio is fairly consistent at about 3:1, carbonate content varies widely within Europe, for example, <11% in

Poland, 12–15% in The Netherlands, 5–20% in east Kent (UK), <12 to >20% in northern France, and up to 25% at some sites in western Germany. Carbonate is present in both clastic and secondary forms, the latter occurring as concretions ('loess dolls'), pore linings, encrustations, and intergranular cements.

The finest fractions (clay grade: <2 µm) of loess and paleosols are rich in clay minerals, and also include varying amounts of lithic and biogenic quartz. Kaolinite and illite are the most common clay minerals, together with chlorite, vermiculite, smectite, and several mixed-layer clays. Clay species vary regionally in response to source-area rock composition, sorting during transport, and postdepositional weathering. Smectite/illite is prominent in the loess of southern Poland (50–80% of the clay grade, the highest values occurring in the older units), with illite (up to 40%) and minor kaolinite (2–5%; [Grabowska-Olszewska, 1988](#)). The smectite group (montmorillonite, nontronite, and beidellite) is also prominent in loess and paleosols in parts of the Ukrainian plains, together with hydromicas, mixed-layer hydromica–montmorillonite minerals, kaolinite and halloysite. Ancillary minerals include chlorite, goethite, calcite, gypsum, and quartz ([Perederij, 2001](#)).

Morphology and Particle Size Distribution of European Loess

Although frequently described as a homogeneous sediment, the bulk properties of loess show important variations with age (i.e., the depth below the surface), location, site, source area, topography, and depositional and weathering history. For example, in regions such as Europe that were subjected to multiple glaciations in the Quaternary, glacial grinding produced abundant 'rock flour' that was deposited by meltwater, and reworked by the wind, as well as by periglacial braided fluvial systems such as the Danube, Dnieper, and Rhine rivers. The mainly mechanical breakage of rock particles into silt-sized (2–63 µm diameter) dust susceptible to deflation yielded particles that are dominantly of tabular and blade shape ([Smalley, 1966](#)). As most of these silt particles are transported in suspension, they lack the edge-rounding and 'frosted' surface texture so characteristic of wind-blown sand grains. Partly rounded particles in loess tend to be nonquartz components, including grains arising from certain secondary (chemical) postdepositional processes. The quartz grains in some of the loess in Normandy, France, and the Channel Islands are subangular in shape, but appear rounded because they are almost completely mantled in a clay coating rich in Si, Al, and Fe.

Sediments described as loess in Europe show a wide range of particle sizes. Leaving aside intraregional variations arising from distance from sources, silt content of loess by weight is generally between 60 and 80%, with <20% clay grade, and

Figure 1 Loess distribution in Europe. sand grades of <15% across a swathe of western European countries. In the loess of the Russian plain and Ukraine, the content of fine silt and clay (<5 μm) in the south is approximately twice than that found further north, the particle size gradients being north–south in the west and northwest–southeast further to the east. Higher clay contents are generally found between the Volga and the Ural Mountains (Rozycki, 1991). A southeast-to-northwest particle size gradient, resulting from the northwestward advection of fine dust from the Caspian–Aral depression, is evident in southeast Europe; this transition zone runs northeastward from Bucharest, and marks the border between the Caspian–Black Sea loess zone and the western European loess supplied from dominantly Atlantic westerly (proglacial) and subsidiary southerly (Saharan) dust sources (Figure 2; Rozycki, 1991). Stratigraphically important volcanic tephra are present on both sides of this transition zone – the Eifel tephra, on the west side, indicating transport by the (south) westerlies, and those from the Caucasus carried by southeasterly winds. Other tephra have been identified in European loess series as, for example, the volcanic ash fallout of the Bag tephra in Hungarian loess during marine isotope stages (MISs) 10 and 8, and the tephra layer identified in the MIS 3 loess in the Paks sequence (Frechen et al., 1997; Horvath, 2001). More recently, in Germany, the loess sequences of the Rhine Valley (Nussloch) have been shown to record the Etlviller tuff (Semmel, 1967) fallout during loess deposition in late MIS 2 (Antoine et al., 2001) contributing greater precision to the discussed age of this ash layer (Juvigné and Wintle, 1988; Zöller et al., 1988).

The loess of western Europe varies with age and geographical location. Loosely packed coarse to medium angular silts, with little clay mineral content and limited, often localized cementation (comparable to much Asian loess), can be found at many sites in continental Europe. Thus, fabric varies with

climatic type and variation through time, not only with changes between soil saturation and desiccation as well as the freeze-drying associated with cryoturbation (Van Vliet-Lanoë and Coutard, 1984), but with a suite of other processes including bioturbation, leaching and redeposition, snow meltwater infiltration, mineral weathering, natural loading and unloading, and reworking by running water and mass movements on

slopes. Preferred fabric trends (anisotropic fabrics) are quite common in European loess. They range from visible lamination (as in alluvially redeposited loessic silts; Derbyshire and Mellors, 1988) to the strongly parallel particle fabrics generated *in situ* by cyclic freezing and thawing. *Limon à doublets* is a distinctive, noncalcareous loess facies found from the Channel Islands off the Normandy coast in the west to the Russian Plain in the east. Its distinctive fabric consists of thin, gently dipping alternating laminae of brown, clay-rich and gray, clay-poor layers, between 1 mm and >1 cm thick (Derbyshire et al., 1988). The 'doublets' features are widely regarded as postsedimentary in origin, having been interpreted as thin layers enriched by pedological clay overprinted on previous grain size discontinuities, the concentration of clay and silt particles on lamellar freeze-thaw features having followed rapid decay of the permafrost at the end of the last glacial.

Calculation of mass accumulation rates (MARs) for loess of the last glacial period (~28–13 ka BP) at over 30 sites across Europe (Frechen et al., 2003) has indicated variable accumulation rates ranging from ~100 to 7000 g m⁻² year⁻¹ along an increasingly continental east–west transect. Making allowances for variation in regional and local silt sources as well as precipitation and wind patterns, which tend to result in the highest individual accumulation rates occurring on terraces of major rivers such as the Rhine, a general pattern emerges in which the lowest mean rates occur on the northwestern periphery of Europe in France and Belgium (~100–600 g m⁻² year⁻¹), with higher accumulation rates evident toward the southeast, in the Czech Republic, Austria, and Hungary (800–3200 g m⁻² year⁻¹).

Loess of Europe: The Origin

Atmospheric dynamics in Europe during the last glacial period were probably very different from those of today because of the presence of extensive and thick ice sheets. Thus, air masses were channeled into a west-to-east trending corridor along the 50° N parallel that broadly corresponds to the main loess-deposition belt in Europe. To the east of the Carpathians, in contrast, elevated terrain gives way to the western lowlands of Ukraine and Tajikistan. Here, reduced topographic constraints on air-flow resulted in a mode of loess deposition quite different from that in the west.

Based on the comparison between the loess zones and mineralogical data (heavy minerals and silts), it is possible to locate the main source of Weichselian (last glacial age) loess in Europe. These studies show that loess in northwestern Europe originated from the North Sea, the central part of the English Channel, and Brittany (eastern English Channel, westward of the Cotentin peninsula). On the other hand, there were also local contributions, linked to the deflation of the main alluvial plains (Seine, Oise, Aisne, Marne, and Somme), which were mixed with particles from the bedrock substratum (frost-shattered chalk and sand). There were also contributions from the dried-out and extended paleoestuaries of the Seine and Somme rivers, and from the wide alluvial braided floodplains of periglacial valleys.

According to Lautridou (1985), eolian deflation during the Weichselian should have prevailed in the large estuaries located 20–30 m below present sea level in the English Channel, which were partially preserved during the maximum lowering of sea level at the Last Glacial Maximum (LGM). In this context, loess sedimentation in northern France should have been supplied by deflation, which prevailed in the paleoestuary of the Somme River, and on the dense paleochannel system of the eastern Channel (Antoine et al., 2003b; Auffret et al., 1982). In addition to these sources of loess, there were more local contributions, originating from the Oise, Marne, Meuse, or Rhine Valleys. In Belgium, study of heavy minerals has shown that the main source of the Weichselian loess was the floor of the North Sea, which, at that time, consisted of sets of braided channels carrying the outwash of the Fennoscandian Ice sheet (Juvigné, 1985). Quite apart from any climatic factors, loess sedimentation in Europe was controlled by sources of available dust. Thus, the main zones of deflation identified in Europe are the dried-out plains (paleoestuaries) of the English Channel and the North Sea where it was exposed by sea-level lowering. Southward, the northern part of the Adriatic Sea at the mouth of the Po River played a similar role. Other sources include the alluvial plains occupied by braided channels during the Pleniglacial phases (times of maximum ice extent, roughly from 70 until 12 ka BP) of the last glacial period. In these fluvial systems typical of periglacial environments, the numerous sandy bars, with sparse vegetation between channels, were probably subjected to intense eolian deflation. The Ukrainian loess, to the south of Kiev, probably originated in such a manner.

The European loess deposits occur as three main morphological types corresponding to the depositional environment and the presence of sedimentary traps.

1. The platform loess, or 'cover loess,' in western Europe, occurs as a mantle of relatively constant thickness. This loess is a homogeneous facies, characterized by considerable spatial continuity that corresponds to the coldest and driest phases of the upper Pleniglacial of the Weichselian (~30–15 ka BP).
2. Slope deposits – more localized, and of variable thickness – are preserved in sedimentary traps. This loess is deposited leeward of asymmetric valleys, features that occur frequently in Europe; loess deposition is influenced by a combination of valley orientation and wind direction. Dust accumulates on the leeward slope, where landform-induced turbulence allows dust to settle and where snow cover and local vegetation act as dust traps. In contrast, windward slopes are zones of deflation (nondeposition). Such phenomena also occur in a variety of local settings, including alluvial terraces and the acute slope angle between marine cliffs and fossil beaches, such as at Sangatte (northern France). The famous sequence at Red Hill near Brno shows the succession of several cycles of loess slope deposits linked to alluvial terraces. Kukla (1977) reviewed several such deposits in Europe.
3. A third dune-like morphology, known as loess Greda, is linked to platform loess. Loess Greda look like elongated dunes several kilometers long; they have been described in central Europe by Léger (1990), and have also been

observed on the right bank of the Rhine Valley near Heidelberg (Antoine et al., 2001). In the latter location, loess accumulation is mostly represented by upper Pleniglacial deposits (35–15 ka), which reach a thickness of 15–20 m; Greda are oriented NNW–ESE, with small, discrete valleys between them.

Paleosols and Their Stratigraphic Significance in the Loess of Europe

The different loess units show a fundamentally cyclic climatic origin (Kukla, 1977). This cyclicity is expressed as an alternating series of loess and paleosols that correspond to global glacial–interglacial climate cycles of 100-ka average duration for the most recent ones (Kukla and Cilek, 1996). Every cycle has a forest soil B-horizon, which is overlain by a steppe (chernozem) soil in central and eastern Europe, and a humiferous forest soil in western Europe. In slope deposits, a light-colored dust layer overlies the black humiferous horizon abruptly; it is overlain by a pellet sand layer, which is capped by loess deposits. In ‘platform’ settings, this sequence is not so apparent; the slope deposits, which have preserved a much more complete record of past environmental changes, are more informative than those in platform settings. Platform deposits contain only direct airfall loess trapped by the local vegetation. Six stages in the development of soil complexes in loess have been summarized by Kukla and Koci (1972) (Figure 3). The recognition of the different soils provides information on the paleoenvironmental conditions, and also provides a very useful tool for section-to-section correlation.

Many European loess studies have shown that abrupt changes in sedimentation are recorded in soil complexes as ‘markers.’ Markers are generally finer grained than normal loess but have no significant differences in composition (Hradilova and Stastny, 1994). An intriguing problem raised by markers is that of identification of the dust source which, given its fine grain size, may not have been close by (Rousseau et al., 1998a). Markers may represent long-distance eolian

transport because of their characteristic sharp contacts and much finer grain size. Thus, dust storms of continental magnitude seem to offer a possible explanation for the deposition of markers. Several studies report major dust events in historical time. Kukla (1977) reported that, on 5 April 1960, a storm deposited 3 cm of dust in Romania, carried from the Kalmyk steppe in Central Asia, for example, a distance of more than 2000 km. Several dust storms have also transported red dust from the Sahara to Europe during the past 20–30 years.

While loess sequences of the last climatic cycle are the best preserved in Europe, some loess–paleosol sequences show older cycles. In northwestern Europe, the St. Pierre-lès-Elbeuf sequence in Normandy shows four cycles (Lautridou, 1974), overlying a tufa with a mollusk fauna of probable MIS 11 (~400 ka) age (Rousseau et al., 1992). The Somme Valley shows overlapping loess and paleosol sequences that overlie the different river terraces (Antoine, 1994). The oldest (sandy) loess, located on top of the terrace dated at about 1 Ma, was deposited at the end of the Lower Pleistocene before the B–M magnetic reversal (Antoine et al., 2000, 2003a). The St. Vallier loess, near Lyon, is among the oldest in Europe, having been dated to 2.5–1.8 Ma by means of a tephra horizon of the Mont Dore volcanic system (Pastre et al., 1996). In the Rhine Valley, the Achenheim loess includes five loess–paleosol couplets, rich in terrestrial mollusks (Lautridou et al., 1986; Sommé et al., 1986). This sequence contains a yellow loess (the ‘canary loess’) that corresponds to MIS 12 (Rousseau, 1987), and indicates particularly cold conditions. Finally, in central Europe, the Krems and Red Hill sequences (Czech Republic) are famous for the long climatic history they preserve, stretching back to the Brunhes–Matuyama boundary at about 0.75 Ma (Kukla, 1977). The loess sequence at Starnzendorf (Austria) records the Gauss–Matuyama paleomagnetic boundary at about 2.5 Ma (Kukla et al., 1990).

Dating Loess in Europe: Geochronology

Most European last glacial loess chronology is based on luminescence dating methods, which include thermoluminescence (TL), optically stimulated luminescence (OSL), and infrared stimulated luminescence (IRSL) (Lang et al., 2003; Wintle et al., 1984; Zöller and Wagner, 1990). As the electron traps involved in these different solid-state physics processes appear to behave almost independently, several age determinations can be obtained from the same sample.

In Europe, the most common materials used for ^{14}C dating are charcoal and wood. These materials are uncommon in loess, and are rarely distributed in an order that provides a continuous, high-resolution chronology. A chronological framework was developed for the Nussloch loess sequence in Germany, based on AMS ^{14}C dating of loess organic matter (Hatté et al., 2001a). The protocol used in this study is adapted to the particular characteristics of the Nussloch sequence (low organic carbon content, high carbonate content, and iron under +2 oxidation state; Hatté et al., 2001b). The resulting radiocarbon chronology is in excellent agreement with OSL ages, although the two chronological methods do not date identical events. Indeed, since luminescence techniques measure the time elapsed since the last sunlight bleaching event,

Figure 3 Schematic development of soil complex in loess areas. Reproduced from Kukla G and Koci A (1972) End of the Last Interglacial in the loess record. *Quaternary Research* 2: 374–383.

and thus characterize pulses of dust, ^{14}C on loess organic matter determines the time elapsed since the death of the plant that grew and died on a loess surface before being covered by a new dust pulse. There is no notion of pulse for ^{14}C chronology since vegetation is always present. The general difference between luminescence and ^{14}C chronologies can be summarized by saying that the first characterizes a temporal framework in steps whereas the second smooths and somewhat leads the first one (Figure 4).

Variability of Loess Sedimentation within a Single Glacial Period (Last Climatic Cycle) in Western Europe

Stratigraphic, paleopedologic, mollusk, and palynologic data, coupled with sedimentology, magnetic susceptibility, and TL/IRSL ages, provide a new picture of the last climatic cycle in northwestern Europe, and its connection with neighboring regions (Figure 5). The last interglacial period (including MIS 5e and part of MIS 5d; Kukla et al., 1997) in Europe is

called the Eemian. After the truncation of the Bt horizon that formed in the Eemian paleosol (the Rocourt soil), the early Weichselian is represented by a complex of humiferous paleosols, known as the St. Sauflieu soils (Antoine et al., 1994). This complex is characterized by the superimposition of a gray forest soil, locally doubled (Bettencourt-St. Ouen, Villiers Adam) and two or three steppe soils. The lower part, with its gray forest soils, correlates with the Brörup/Rederstall/Odderade succession (MIS 5d/5a; Figure 6). This sequence indicates a first continentalization of the environment, with development of gray forest soils in loess-derived colluvium, under a boreal forest of pine and beech (Munaut in Antoine et al., 1994, 1999). Above an erosional phase with evidence of deep seasonal frost (the end of MIS 5a), the upper part of the complex is characterized by soils that formed under some birch in a steppe environment with grass and aster family plants. This part of the pedocomplex probably represents the rapid climatic oscillations that prevailed during the transition between MIS 5 and 4 (interstadials 20 and 19 of the GRIP ice-core record; Dansgaard et al., 1993). The whole paleosol

Figure 4 Comparison between the OSL and ^{14}C dates in the upper Pleniglacial sequence of Nussloch. Key to symbols: G, gley horizon; ET, Eltville Tuff. Data from Hatté et al. (2001a) and Lang et al. (2003).

Figure 5 Pedostratigraphy of the upper Pleistocene in western Europe. Reproduced from Antoine P, Rousseau DD, Lautridou JP, and Hatté C (1999) Last interglacial–glacial climatic cycle in loess–paleosol successions of north-western France. *Boreas* 28: 551–563.

sequence shows an increasingly continental environment in two main phases, contemporaneous with sea-level lowering (Sommé et al., 1994). Thus, the paleogeographic change in the North Sea–Channel region contributed to the disappearance of the oceanic influence at the end of the last interglacial.

The upper boundary of the early glacial is defined by the erosive contact at the top of the last steppe soil (Antoine et al., 1994). After the deposition of the first loess (the lower Pleniglacial), an extensive but short erosive episode is marked by laminated colluvium with soil fragments, cryoturbation, and frost cracks, which indicate frost reworking of the underlying levels. This unit, up to 2 m thick in northern France, is a marker level in the oldest part of the Weichselian. A similar record can be traced all the way to the Rhine Valley (Antoine et al., 2001; Haesaerts et al., 2005).

The lower Pleniglacial loess is locally covered by younger loess, often heterogeneous and containing granules. Above this loess, a soil complex is found (Complex of St. Acheul–Villiers Adam) that corresponds to most of the middle Pleniglacial (MIS 3, 50–30 ka). During this period, loess sedimentation diminished and was interrupted by several phases of pedogenesis. These phases produced brown boreal soil to arctic brown soils.

In most of the profiles in the Somme and Normandy, this period is represented by a unique polygenetic horizon (St. Acheul).

Elsewhere, in the sequences found in Villiers Adam, the loess is thicker (4 m) and contains four paleosols: a leached boreal soil, a humiferous arctic meadow soil (Van Vliet-Lanoë, 1987), a tundra gley, and an Arctic brown soil.

The lowermost part of the upper Pleniglacial loess marks the end of pedogenesis; it contains frost wedges and evidence of thermokarst (Antoine et al., 2001). Following that, the main body of the upper Pleniglacial loess was deposited between ~25 and 15 ka. Typically, these deposits are about 4–5 m thick, but may locally reach 6–8 m in thickness. The upper Pleniglacial loess contains as many as three units, separated by periglacial paleosol horizons (Antoine, 1991). The most common unit is the Nagelbeek/‘Kesselt’ tongue horizon, dated to about 22 ka ^{14}C year (Haesaerts et al., 1981). The modern soil is developed in the uppermost upper Pleniglacial loess. A high-resolution investigation in some western European loess has documented climate variability through different indices (biological, sedimentological, geochemical, and geophysical). The results show that during the last climatic cycle, the main loess deposition interval started at ~70 ka

Figure 6 Paleosol complex of St. Sauflieu including the last interglacial paleosol and the humiferous soils of the early Pleniglacial. Photo by Pierre Antoine.

and ended at $\sim 16\text{--}15$ ka (Rousseau et al., 1998b). Two main phases of loess deposition, centered around 60 ± 5 and 23 ± 8 ka BP, are separated by a period with much lower sedimentation rates of between ± 55 and 35 ka (Antoine et al., 1999, 2001).

A similar sequence, with local variations due to the more continental conditions inferred from their geographical location, is available for central Europe (Kukla, 1977; Figure 7). A brown forest Bt soil at the base corresponds to the last interglacial. It is overlain by a biogenic steppe soil of chernozem type, interrupted by a Marker I, 2–10-cm thick. This is a sharply delimited band of light-colored dust. It separates the underlying chernozem from the overlying hillwash loam composed of sand-sized fragments known as pellet sands. Fine loess caps this first pedocomplex (PKIII). This first eolian deposit is succeeded by a second pedocomplex (PKII) with a pseudogley overlain by a chernozem interrupted in some rare places by a new Marker horizon (IIa), immediately followed by small pellet sands capped by another loess. This succession is repeated a second time with a thicker chernozem interrupted by Marker II, overlain, in turn, by thick pellet sands and a loess with an age placing it at the base of MIS 4. A third soil complex developed after this lower Pleniglacial loess; it consists of a brown decalcified soil overlain by a thin loess, then a humiferous chernozem. This is pedocomplex PKI. Finally, the upper Pleniglacial displays the thickest loess deposits, with intercalated gley horizons, as observed in western Europe. A similar pattern, with regional differentiation, has also been described in the Ukrainian loess deposits near Lubny (Rousseau et al.,

Figure 7 Pedomatigraphy of eastern Europe. Reproduced from Kukla G (1977) Pleistocene land-sea correlations. 1: Europe. *Earth-Science Reviews* 13: 307–374; Rousseau DD (2001) Loess biostratigraphy: New advances and approaches in mollusk studies. *Earth-Science Reviews* 54(1–3): 157–171.

2001). At Lubny, the loesses and paleosols correlate closely with those of central (Kukla, 1977) and western Europe. Thus, there is a remarkable consistency in the history of the last climatic cycle as recorded in the loess sequences of western, central, and eastern Europe over a distance of 2500 km, as shown by Haesaerts et al. (2003, 2005). The differences observed relate to local conditions arising from the proximity of the Fennoscandian ice sheet and Alpine glaciers, or the influence of the westerlies and climatic variations over the North Atlantic.

Paleoclimatic Proxies in European Loess

The past few decades have seen the development of new paleoclimatic proxies, allowing a more precise interpretation of the European loess sequences. These include loess and paleosol geochemistry, identification of periglacial features, molluscan paleozoogeography, magnetic susceptibility, and detailed sedimentology.

Geochemistry

Few organic geochemistry investigations are available for European loess, but several recent studies of loess have been completed in France (Hatté, 2000; Hatté et al., 1998) and Germany (Hatté and Guiot, 2005; Hatté et al., 1998, 1999, 2001a; Pustovoytov and Terhorst, 2004). Other investigations are in progress in eastern Europe. Organic geochemistry studies

are based on the 'fingerprint' of environmental conditions provided by plant $\delta^{13}\text{C}$, and on its undisturbed conservation during burial and subsequent sedimentation. During photosynthesis, plants discriminate against ^{13}C because of differences in chemical and physical properties due to its greater mass (O'Leary, 1981). Both major types of photosynthetic pathways have a characteristic isotopic signature. C4 plants living in rather severe climatic conditions, with high insolation and/or water stress, show a mean $\delta^{13}\text{C}$ of $-13 \pm 2\text{‰}$, whereas C3 plants, which prefer more temperate environments, present $\delta^{13}\text{C}$ values around $-26 \pm 4\text{‰}$ (O'Leary, 1988). Variability around the mean $\delta^{13}\text{C}$ values in leaves of terrestrial vegetation (foliar $\delta^{13}\text{C}$) results from environmental changes that influence stomatal conductance (e.g., Feng and Epstein, 1995). These results show that variation of the $\delta^{13}\text{C}$ in C3 plants within the range -30 to -22‰ is primarily influenced by the $\delta^{13}\text{C}$, the concentration of atmospheric CO_2 , and by precipitation, and, second, by soil type and texture and insolation. Temperature influence differs from one biome (association of plants) to another, but remains the most important parameter in the definition of the biome itself. On the other hand, variations of isotopic signature in C4 plants within the -15 to -11‰ interval must be almost exclusively linked to variations in the $\delta^{13}\text{C}$ in atmospheric CO_2 . All these metabolic responses to environmental changes indicate that carbon isotopic composition of plants reflects climatic variations.

In contrast to interglacial soils, typical loess is associated with sparse vegetation and a weak rhizosphere. The absence of well-established pedogenesis and the dry glacial environment favor the degradation of organic matter without distortion of the isotopic signal, making typical loess suitable for an organic geochemical study. When properly prepared (Hatté and Gauthier, 2006), the carbon isotopic composition of loess organic matter is a powerful paleoclimatic indicator, because it inherits the $\delta^{13}\text{C}$ of growing plants that trap dust at the time of deposition. As environmental conditions and vegetation types (C3 vs. C4 photosynthetic pathways) control the $\delta^{13}\text{C}$ levels in plants, the $\delta^{13}\text{C}$ values of organic matter in loess can be used to infer temporal variations in climate and vegetation. Thus, the isotopic signal cannot be interpreted solely in terms of change in the ratio of C3 to C4 plants. Indeed, considering only the C3 photosynthetic pathway, $\delta^{13}\text{C}$ variations can be linked to first order changes in atmospheric CO_2 ($\delta^{13}\text{C}$ and concentration) and precipitation and, at the second order, to temperature, soil type and texture, and insolation.

In the Rhine Valley (Achenheim, France, and Nussloch, Germany), Hatté et al. (1998) demonstrated, with values ranging from -23 to -26‰ , C3 origin of organic matter during the last glacial period (70–12 ka BP), whereas Pustovoytov and Terhorst (2004) exhibited some C4 carbon-enriched layers ($\delta^{13}\text{C}$ from -16 to -19‰) within the same period in Schattenhausen, <1 km to the east of Nussloch. This conflict of view remains to be resolved, but two interpretations can be proposed. One concerns complications arising from carbonates in the loess. Another possibility is that there existed a mosaic of vegetation types, such as a mixture of C4 grasses and C3 trees.

Considering the C3 photosynthetic pathway only, Hatté et al. (1998, 1999) interpreted the variations in the $\delta^{13}\text{C}$ of loess organic matter in Nussloch (Germany, Rhine Valley) and

Achenheim (France, Rhine Valley) as a response to changes in paleoprecipitation during the last glaciation. Using a linear relation between loess $\delta^{13}\text{C}$ and atmospheric CO_2 concentration and $\delta^{13}\text{C}$, on the one hand, and precipitation on the other, Hatté et al. (2001b) attempted a deconvolution of the loess $\delta^{13}\text{C}$ record to reconstruct paleoprecipitation. However, paleoclimatic inferences were limited because only parameters of the first order were taken into account. Nevertheless, use of a vegetation model (Biome4) provides the required greater complexity by considering first- and second-order parameters. Inverse modeling of loess $\delta^{13}\text{C}$ in Nussloch provided reconstructed paleoprecipitation values that varied between 240 and 400 mm year $^{-1}$ through the last glaciation (Hatté and Guiot, 2005). This clearly demonstrated atmospheric teleconnections with the Greenland ice sheet extension, by matching Dansgaard-Oeschger (D/O) events with a precipitation increase of ~ 100 –200 mm year $^{-1}$ (Hatté and Guiot, 2005; Figure 8).

Cryoturbation and Evidence of Ice Wedges

Cryoturbation features and ice-wedge casts occur at different stratigraphic levels in the northwestern European loess sequences, and represent marker horizons that allow correlation of sections (Lautridou and Sommé, 1974). Following the studies of Pissart (1987) and Van Vliet-Lanoë (1987), cryoturbation features are interpreted as the result of differential expansion of different surface materials in response to freezing. Indeed, in contrasting materials (e.g., loam vs. sand), the experiments performed in Caen indicate clearly the establishment of structures with a drop or pear shape when the pressure generated by this process is blocked at the surface by refreezing. In poorly drained environments with a surface water sheet, the cryogenic expansion, blocked by surface freezing, causes downward deformation. Conversely, in a well-drained environment, the cryogenic expansion can exert a force toward the surface, and so produce certain relief forms (tundra ostioles, soils with ice mounds).

Ice-wedge casts are produced from cracks caused by thermal contraction. They form progressively in a series of events, as follows: (1) cracking of the permafrost by thermal contraction in winter and (2) infilling of cracks with meltwater produced by thawing of snow in spring, followed by refreezing (French, 1996; Péwé, 1962). The development of these structures indicates the occurrence of permafrost, with a mean atmospheric temperature lower than -8°C , and lack of a thick snow cover. After the degradation of the ice wedge, the structure is often fossilized by loess sedimentation. The ice-wedge casts can be as large as 1 m wide and 2 m deep in the loess of northern France and Belgium (Figure 9). In plan view, ice-wedge casts make up a network of polygons ± 10 –12 m wide. Their presence in the loess indicates significantly colder temperatures during the last glacial period.

Terrestrial Mollusks and Paleozoogeography

Terrestrial mollusk (gastropod) assemblages are one of the most powerful paleoclimate proxies in carbonate loess sequences (Figure 10). Quaternary mollusk species are extant and do not show any changes in their ecological requirements.

Figure 8 Reconstruction of annual precipitation in the Nussloch sequence. Reproduced from Hatté C and Guiot J (2005) Paleoprecipitation reconstruction by inverse modelling using the isotopic signal of loess organic matter: Application to the Nussloch loess sequence (Rhine Valley, Germany). *Climate Dynamics* 25: 315–327.

Figure 9 Ice wedge in the loess sequence at Sourdon. Photo by Pierre Antoine.

As the identification of the species is performed by considering the shell shape and ornamentation, it is then possible to use the present ecological requirements and zoogeography of living individuals to interpret the fossil assemblages. Variations

in the specific composition of gastropods can be used to characterize past environments, and to reconstruct ecological and climatic parameters. Mollusk communities, including forest species, mainly represent temperate assemblages regardless of the region under consideration. Interstadial assemblages include species indicating cool and open conditions, whereas two main assemblages represent cold environments (Lozek, 1990; Rousseau, 1987, 2001; Rousseau and Puisségur, 1990). One group best characterizes steppe environments and is dominated by four species of *Pupilla*. The coldest and wettest conditions of a tundra-like environment are represented by the *Columella* group, which includes more species than the *Pupilla* group. While climatic variations can be interpreted from multivariate analysis of the mollusk assemblages, the compilation of the assemblages over a large area also yields other important information. Indeed, the impoverishment of the mollusk assemblages in the western European Upper Pleistocene loess sequence has been interpreted as a response to the coldest and wettest condition that prevailed in this area. In contrast, conditions notably less maritime (Atlantic) characterized central Europe during the last glacial period, where the assemblages were both more abundant and more diverse (Rousseau, 2001; Rousseau et al., 1990). Transfer functions of terrestrial mollusks, following the modern analog principle, have been developed for European loess sequences, which show similar temperature reconstructions to those computed from pollen counts (Rousseau, 1991). Other methods have also been developed using the present distribution of the species, as well as the 'climate mutual range' method originally developed for beetles (Moine et al., 2002). Finally, studies of Hungarian mollusk assemblages have used the ecological ranges of the observed species, applying a

Figure 10 Main terrestrial mollusk species described from loess deposits. Photos by O. Moine.

method similar to the one developed for micromammal studies by Okhr (Sümegei and Hertelendi, 1998). Terrestrial mollusks have also been studied for their amino acid signatures, which show significant differences from one climatic cycle to another (Oches and McCoy, 1995).

Sedimentology and Grain Size

The particle size distribution of loess is often used to determine variations in the composition of the sediment. However, variation in the different grain size classes can also be used to determine the relative wind velocity at the time of particle transport. Comparison of the different grain size classes, from silt to coarse sands, is widely used in loess studies. Shi et al. (2003) interpreted an increase in the coarser grain size fractions at Dolni Vestonice (Czech Republic) as corresponding to the record of the major iceberg discharges in the North Atlantic, called Heinrich Events. However, another approach is to define a grain size index, which corresponds to a ratio of two main particle size classes. Higher values indicate stronger winds. Two main indices have been developed. Studying the loess sequence at Kesselt in Belgium, Vandenberghe et al.

(1998) defined the 'U ratio' as the ratio between the two size classes 16–44 and 5.5–16 μm . Similarly, in studying other European loess sequences, Antoine et al. (2002) developed the IGR index ratio defined as the ratio between coarse loam (20–50 μm) and fine loam and clay (<20 μm), which is similar to the 'U ratio.' The IGR index can be used not only to reconstruct the wind dynamics but also as a new tool for the detailed correlation of different sequences within a limited area or along a transect. Results of studies using this method indicate that similar patterns can be traced from west to east right across Europe from northern France to Ukraine.

European Loess as a Record of the Response of the Continental Environments to North Atlantic Climatic Variability

Loess sedimentation in Europe appears to be rhythmic. Compared to Chinese loess, the European loess sequences (and especially those in western Europe) show a more discontinuous and contrasting record. These characteristics are linked to the influence of the North Atlantic Ocean that gives rise to

Figure 11 Comparison of the IGR grain size index at Nussloch and the GRIP dust record during the 35–15-ka interval. Reproduced from Rousseau DD, et al. (2002) Abrupt millennial climatic changes from Nussloch (Germany) Upper Weichselian eolian records during the Last Glaciation. *Quaternary Science Reviews* 21(14–15): 1577–1582.

more humid environments (increase in soil development, and periglacial structures) and to high-frequency (millennial) variations in loess depositional rates.

According to new studies, the loess of Europe records rapid climatic events similar to those described in the Greenland GISP2 and GRIP ice cores (D/O), and in marine cores from the North Atlantic (Bond cycles). The latest results (Hatté et al., 2001a; Lang et al., 2003) obtained in studies of the Nussloch loess sequence (Germany) indicate good correspondence between European loess and North Atlantic climate variability (Antoine et al., 2001, 2002; Rousseau et al., 2002; Figures 11 and 12).

The cornerstone hypothesis of the study of the Nussloch sequence in the Rhine Valley is that loess sedimentation, if it has global significance, should be coherent with the dust record preserved in Greenland ice. High-resolution analyses of the Nussloch loess sequence can best be compared to the Greenland dust record because both provide a record of Northern Hemisphere eolian dynamics. Both GRIP and GISP2 dust records show alternating phases of high or very low dust concentrations in the atmosphere, the latter corresponding to the D/O interstadial (IS) events (IS 2–24 of Dansgaard et al. (1993), being warm climatic intervals during which very little dust reached Greenland).

Measurements of magnetic susceptibility and pedostratigraphy show clearly that the succession of loess and paleosols at Nussloch matches the general stratigraphy of the last

climatic cycle in western Europe. This succession, dated by AMS radiocarbon and OSL, has been correlated with the GRIP dust concentration for the last climatic cycle (Figure 11). Numerous events in the Greenland record corresponding to D/O events also appear to be recorded in the loess sequence (Figure 10).

At Nussloch, the variations of the IGR index through time appear similar to the fluctuations in Greenland dust fluctuation during the 32–19 ka interval, where the temporal resolution is best (Figure 11). Furthermore, similar and synchronous variations have been determined in other western European sequences (Achenheim, Mainz-Weisenau) within the EOLE project (CNRS-ECLIPSE program), providing support for the global value of the IGR grain size index used. Thus, it appears that the western European loess sequences faithfully record D/O events, with the Nussloch section rightfully considered as a key reference locality (Antoine et al., 2002; Rousseau et al., 2002). However, this record of the D/O events is a function of the strength and duration of interstadial warming, as is also expressed in the $\delta^{18}\text{O}$ values in Greenland ice cores. Work within the EOLE project indicates that the warmest and longest interstadials are marked by well-developed paleosols (Bw horizon at the base of the thick sequence). In contrast, if the duration of the period of low dust concentration is short, then the interstadial will be marked in the stratigraphy by a gley paleosol, the signature of which will depend on the strength of the corresponding warming.

Figure 12 Pedostratigraphy of the Nussloch sequence compared with the Greenland dust record. Reproduced from Antoine P, et al. (2001) High-resolution record of the last interglacial–glacial cycle in the loess paleosol sequences of Nussloch (Rhine Valley–Germany). *Quaternary International* 76/77: 211–229; Rousseau DD, Antoine P, Hatté C, and Moine O (2003) Enregistrements des événements rapides de type Dansgaard–Oeschger dans les séquences loessiques européennes. *Lettre pigb-pmrc-France* 15: 21–24.

Variations in organic matter $\delta^{13}\text{C}$ support this interpretation, having been mainly linked to climatic fluctuations (availability of water and atmospheric CO_2 concentration) as recorded by the vegetation (Hatté et al., 1998, 2001b). Warming during D/O events is also marked by larger terrestrial mollusk populations, as indicated by a greater abundance of counted individuals. Although the loess record and its correlation with Greenland is well documented at Nussloch, similar patterns, especially in the stratigraphy and also in the grain size variations, have been described all along the loess belt from northern France eastward to the Czech Republic and Ukraine, demonstrating again that European loess has faithfully recorded the climatic variations that occurred in the North Atlantic.

Summary

The loess of Europe is mostly an eolian sediment, generally presenting elements of both local and global origin. It is indicative of periglacial environmental conditions, which made the fine material available to wind transport, originating mainly from sandurs or dried-out braided rivers, moraines, or

dried-out shelves. Considering their distribution, thickness, and complexity around the margins of the Quaternary ice sheets in the Northern Hemisphere, loess sequences can be considered as one of the best records of global environmental changes on the continents.

European loess sequences have been intensively studied for many decades, but increasingly higher stratigraphic resolution and availability of a growing range of climate proxy indicators have resulted in some notable advances in recent years. Climatic variability has been analyzed at high resolution based on different proxies. Sequences studied have revealed that the main loess deposition started at about 70 ka and ended around 16–15 ka. For example, the magnetic susceptibility record of the Achenheim loess sequence (France) has been correlated with the Upper Pleistocene (70–15 ka) Greenland dust content. Other results have shown that abrupt changes, named markers, are also recorded in the soil complexes. Markers are generally finer grained than most loess, but mineral content does not differ significantly. These markers correspond to long-distance wind-transport episodes, recording clearly visible events. The results from the study of the Nussloch sequence (Rhine Valley) show that the loess sedimentation, *in sensu*

stricto, is rhythmic, its fluctuations corresponding with rapid events of both marine and glacial type.

Analysis of particle size variation is a key method in loess research. Preliminary comparison of the grain size record from the Nussloch sequence, in the Rhine Valley, and the dust content from the GRIP ice core in Greenland shows high-frequency peaks that correlate with dust content in ~1.5-ka cycles, the main ones being associated with the North Atlantic Heinrich Events. This supports the hypothesis that European loess sequences contain a record of rapid climatic changes. Recently, work on $\delta^{13}\text{C}$ variations in organic matter from European loess sequences has shown that $\delta^{13}\text{C}$ parallels the GISP2 $\delta^{18}\text{O}$ variations, and is interpreted as recording the D/O events. Variation in this index was interpreted as recording the response of the local vegetation to climate changes. However, because there were no changes in the type of photosynthetic pathway, this index is also considered to be a proxy for local annual precipitation. In mid-latitudes, therefore, the dust intervals appear to correspond to periods when, although vegetation cover was reduced, it was adequate to provide sufficient organic matter from which to abstract a signal of biological activity (i.e., mollusks). The Greenland dust record also shows that isotope stages 2 and 4 were dustier than stage 3 and that important variations occurred in the dust content of the atmosphere during the same interval. Some of the oscillations were contemporaneous with the massive iceberg discharges named Heinrich Events.

Introduction

The loess deposits of North America cover extensive areas of the midcontinent, northwestern United States, and Alaska and neighboring parts of the Yukon Territory of northwestern Canada. The loess of North America is derived from both glaciogenic and nonglaciogenic sources, and source areas vary both spatially and temporally. The resultant deposits of wind-blown (eolian) silt and intercalated paleosols preserve important records of past climate and environmental conditions during the Quaternary. The loess deposits may act as both a sink and a source of dust, and recently it has been suggested that loess not only reflects changing climatic conditions, but may also potentially cause climate change through radiative forcing, and also through biogeochemical changes in atmospheric, terrestrial, and marine environments (Harrison et al., 2001).

Distribution and Thickness of Loess Deposits

Loess is extensive over North America, particularly in the midcontinent region, Alaska, and the northwestern United States (Figure 1). The distribution of loess deposits in North America is governed primarily by the balance of supply of suitable sediment and the availability of conditions suitable for accumulation (Muhs et al., 2003); these conditions for accumulation include vegetation and topography (Mason et al., 1999; Pye, 1996); source proximity, wind strength, and direction also influencing the pattern of loess distribution (Muhs and Bettis, 2000). In terms of their spatial extent, the principal areas of North America where loess deposits are preserved are: the midcontinent (incorporating the Great Plains and Central Lowland physiographic provinces) plus the Lower Mississippi Valley and the Wabash and Ohio River Valleys; the Pacific northwestern United States (i.e., the Columbia Plateau physiographic province comprising two areas, the Columbia Plateau of eastern Washington and western Oregon, and the Snake River area of southern Idaho); plus Alaska and the neighboring Yukon Territory of northwestern Canada. The notable absence of areally extensive loess deposit in Canada is due to the fact that most of the area was covered by the Laurentide Ice Sheet (LIS) during the last glacial period. Loess deposits are even lacking in those areas of Canada that were deglaciated first. The reason for this is not well understood, but it is likely that the large proglacial lakes, such as glacial Lake Agassiz, served as the sinks for most glaciogenic silt (Flint, 1971).

Maximum loess thicknesses in the North American midcontinent can exceed 60 m; in the Lower Mississippi Valley, bluffs composed of loess 20–30 m high are common (Markewich et al., 1998), with maximum loess thicknesses

occurring to the east of the valley (Figure 2). In many locations in central North America, loess deposited during the last glacial period (Peoria Loess) accounts for more than 90% of the total loess thickness (Pye, 1987). The thickest known deposits of Late Glacial loess in the world occur in central Nebraska (48 m thickness at Bignell Hill), with considerable thicknesses of Peoria Loess also being found in Iowa (41 m at the Loveland Loess paratype) (Bettis et al., 2003). In the Lower Mississippi Valley, Peoria Loess is 10–20 m thick, but the thickness decreases with distance from the river bluffs, i.e. with distance from the likely source areas. The present thicknesses of older loesses here, however, seem to be more closely linked to geomorphic position and degree of dissection than proximity of source (Busacca et al., 2004).

The loess on the Columbia Plateau (Figure 3) ranges from approximately 0.1 to 75 m thickness, with the thickest deposits being found in an area straddling the eastern Washington/western Idaho border, called 'The Palouse' (Busacca and McDonald, 1994). Loess cover in the Columbia Plateau province beyond The Palouse is thinner and less continuous. Loess deposits also cover large areas to the north and south of the Snake River Plain in Idaho and into western Wyoming. Here, the loess is typically 2 m thick, although it can reach up to 12 m thickness in places (Lewis et al., 1975).

Loess is the most widespread surficial deposit in Alaska (Figure 4), covering many areas below 300–450 m altitude (Péwé, 1975). The thicknesses of the deposits range from a few millimeters in some areas to more than 60 m at Gold Hill, north of the Tanana River near Fairbanks (Péwé, 1955). Loess deposits along the north side of the Tanana valley, and in the lower Yukon River valley are 3–12 m in thickness, while on the Seward Peninsula, deposits are reported to be more than 1.5 m thick and cover 75% of the area (Péwé, 1975). Throughout Alaska, loess deposits are thickest near rivers, with thicknesses decreasing rapidly with distance away from the rivers (Péwé, 1975) and downwind of valley dust sources (Lindholm et al., 1959; Muhs et al., 2004). The transport and deposition of loess are processes that are still active today in Alaska (Figure 5), with most activity being focused along the braided glacial streams of the Delta River (Figure 6), the Knik and Matanuska Rivers, and near the junction of the Tanana and Yukon Rivers (Péwé, 1975).

Stratigraphic Framework and Chronology of Loess Deposits

In the central United States, five major loess units have been identified, representing middle-to-late Quaternary deposition. The oldest unit is termed 'pre-Loveland Loess,' although several

Figure 1 Map of North America showing physiographic provinces and the distribution of Quaternary loess. Loess distribution compiled by the authors from sources given in [Figures 2–4](#).

other names also have been proposed (e.g., Crowleys Ridge Loess, Mariana Loess, and Sicily Island Loess); however, while some extensive and well-preserved pre-Loveland loess is found in parts of the Great Plains ([Mason et al., 2004](#)), these deposits are typically poorly preserved in the Central Lowland and northeastern United States, where they are present at all. The more commonly observed lowermost loess unit present in the central United States is Loveland Loess ([Figure 7](#)), which probably correlates with the penultimate glacial period (Marine oxygen isotope stage 6 (MIS-6); [Forman et al., 1992](#); [Maat and Johnson, 1996](#)) and is usually no more than a few meters thick. Loveland Loess, in turn, is overlain by at least two younger loess units. The older of these two units is of mid-Wisconsin age (MIS-3) and is variably termed ‘Roxana Silt’ (for deposits found in the Central Lowland province), ‘Pisgah Formation’ (Iowa), or ‘Gilman Canyon Formation’ (Great Plains). This mid-Wisconsin age loess is overlain by the late-Wisconsin age (MIS-2) ‘Peoria Loess.’ A Holocene loess termed the ‘Bignell Loess,’ which is typically <2 m in thickness, is also present at some Great Plains locations ([Mason et al., 2003](#)). No Holocene loess unit has been identified east of the Missouri River valley; that is, in the Central Lowland ([Figure 2](#); [Bettis et al., 2003](#)).

Loveland Loess has a soil from the last interglacial period (MIS-5 and part of MIS-4) developed in the uppermost part of it, termed the ‘Sangamon Geosol’ ([Grimley et al., 2003](#); [Markewich et al., 1998](#); [Muhs and Bettis, 2000](#)). This paleosol is typically thick (3–5 m), and morphologically better expressed than the modern surface soil. The upper part of the

mid-Wisconsin loess has also been modified by the development of the ‘Farndale Soil’ in the Central Lowland province, and the equivalent Gilman Canyon Formation in the Great Plains province. Where these loesses are thin, the Farndale and Gilman Canyon Formation are welded to the Sangamon Geosol. Peoria Loess overlies the Farndale Soil (or the Gilman Canyon Formation in the Great Plains). The modern soil is developed in Peoria Loess in the Central Lowland. However, in the Great Plains, where Bignell Loess buries Peoria Loess the Brady Soil is formed in the upper part of the Peoria Loess and the modern soil is formed in Bignell Loess.

While the broad temporal framework of the various stratigraphic units identified in the loess sequences of the central United States as outlined above is reasonably well understood, the specific timing of deposition and cessation of accumulation varies spatially across the region. The timing of Peoria Loess deposition, for example, demonstrates important regional differences, varying from between approximately 30 000–20 000 carbon-14 (^{14}C) years before present (BP) for the onset of deposition, and approximately 14 000–10 000 ^{14}C years BP for the end of deposition, based respectively on maximum- and minimum-limiting radiocarbon dates of the bracketing paleosols ([Bettis et al., 2003](#); [Muhs and Zárte, 2001](#)). Luminescence and beryllium-10 (^{10}Be) ages obtained directly for the Peoria Loess also support these radiocarbon dates (e.g., [Bettis et al., 2003](#); [Roberts et al., 2003](#)). Those areas located close to major loess sources record accumulation of loess earlier than areas at more distal locations ([Bettis et al., 2003](#); [Muhs and Zárte, 2001](#); [Ruhe, 1983](#)). Furthermore, accumulation of loess

Figure 2 Map showing the distribution and thickness of last glacial (Peoria) loess in the midcontinent of North America (Central Lowland and Great Plains physiographic provinces). Redrawn from compilation in Figure 2 of Bettis et al. (2003) and sources therein.

also fluctuated over time, resulting in further local stratigraphic variations (e.g., the formation of weakly developed paleosols within Peoria Loess, indicating brief periods of no deposition) which have not been correlated on a regional scale (Busacca et al., 2004; Ruhe et al., 1971; Wang et al., 2000).

The loess deposits in the Columbia Plateau physiographic province preserve a very different record than those of the central United States, both in terms of duration and likely origins. In the Columbia Plateau area of eastern Washington (Figure 8), loess records may extend as far back as 1–2 Ma (Busacca, 1991) and they preserve many paleosols, reflecting periods of nondeposition and stability between times of more active loess deposition. McDonald and Busacca (1992) defined a regional soil-stratigraphic sequence comprising (from oldest to youngest) the Devil's Canyon Soil, the Old Maid Coulee Soil, the Washtucna Soil, and the Sand Hills Coulee Soil. Furthermore, Busacca and McDonald (1994) ascribed the terms 'L1' and 'L2' to the uppermost and the next oldest loess units in the region, respectively (Figure 9). The uppermost unit, L1, contains Holocene loess and the Mazama tephra (dated to ~7700 cal years BP) which, in turn, are located

above the Sand Hills Coulee Soil; the base of this unit is marked by the Mount St. Helens set S tephra (dated to ~15400 cal years BP). The next oldest unit, L2, contains the Washtucna Soil complex and the Old Maid Coulee Soil, and toward the base of the unit the Mount St. Helens set C tephra provides another useful correlative and chronologic marker. Unit L1 is of late Wisconsin age, while L2 is reported to be of early to middle Wisconsin age (Busacca and McDonald, 1994; Richardson et al., 1997). The oldest of the four soil-stratigraphic units identified by McDonald and Busacca (1992), the Devils Canyon Soil, is located at the top of the next oldest loess unit, L3.

In the Snake River Plain area of the Columbia Plateau physiographic province, at least four Quaternary loess units have been identified, separated by buried soils (McDole et al., 1973). The youngest two Quaternary loess units are separated by a well-developed paleosol, and were informally termed 'Loess A' (uppermost unit) and 'Loess B' by Pierce et al. (1982). Loess A is believed to have been deposited during the late Wisconsin (Forman et al., 1993; Kuntz et al., 1986; Pierce et al., 1982). There is, however, some disagreement regarding

Figure 3 Map showing the distribution of loess and inferred paleowinds in the northwestern United States. Compiled from Lewis et al. (1975) and Busacca and McDonald (1994).

III Bettis.

the age of Loess B; an early Wisconsin age is proposed by [Forman et al. \(1993\)](#), on the basis of thermoluminescence ages, whereas [Pierce et al. \(1982\)](#) propose a penultimate glacial age for Loess B on the basis of the degree of soil development and stratigraphic relations with other well-dated deposits.

The loess deposits preserved in Alaska extend even further back in time than those of the Columbia Plateau province, spanning as many as 3 Ma from the end of the Tertiary and through the whole of the Quaternary Period for some localities in unglaciated central Alaska. This age range is based on fission-track dating of tephra preserved in the loess deposits, coupled with observations of paleomagnetic reversals ([Westgate, 1988; Westgate et al., 1990](#)). Numerous paleosols are preserved in the loess of Alaska ([Begét and Hawkins, 1989; Muhs et al., 2003; Figure 10](#)) and the neighboring Yukon Territory suggesting that deposition rates fluctuated over time. Deposits of loess in central Alaska accumulated both before

Figure 7 Photograph of modern soil, last glacial (Peoria) loess, mid-Wisconsin, last interglacial, and older paleosols near Eustis, Nebraska. See [Maat and Johnson \(1996\)](#) and [Roberts et al. \(2003\)](#) for details on stratigraphy and luminescence ages; paleoclimatic inferences of fossil snails in this section are given in [Rousseau and Kukla \(1994\)](#). Photograph by D.R. Muhs.

and during the last interglacial, the mid-Wisconsin stadials, during the last glacial, through the Holocene, and up to the present day ([Muhs et al., 2003; Péwé, 1975](#)).

Sources of Loess and Timing of Deposition

Loess is classically viewed as a glacially derived sediment, leading to the view that loess deposits denote times of increased glacial activity and the intercalated paleosols indicate warmer interglacial or interstadial periods. However, the loess of North America comes from both glaciogenic and nonglaciogenic sources. The response of the different loess regions of North America to glacial and interglacial conditions varies, with the timing of loess deposition depending on the interplay between various factors including climatic conditions, sediment supply, sediment source, and vegetation cover.

In the central United States, geochemical and isotopic provenance studies have shown that the loess deposits can be of both glaciogenic and nonglaciogenic origins, with changes in source possible over time. For example, Peoria Loess in western Iowa shows two different sources over this period; the oldest Peoria Loess is derived from the Missouri River valley (i.e., glacially derived material), while the younger Peoria Loess is derived from a mixture of local glaciogenic material and distal nonglaciogenic sources ([Muhs and Bettis, 2000](#)). Geochemical and isotopic studies of loess from the central United States have revealed that the composition of Peoria Loess varies

Figure 8 Photograph of typical loess-mantled landscape in the Palouse region of eastern Washington and roadcuts showing loess–paleosol stratigraphy. Photograph by H.M. Roberts.

Figure 9 Loess stratigraphy and luminescence chronology at selected localities in the Palouse region of the Columbia Plateau region of North America. Redrawn from Richardson CA, McDonald EV, and Busacca AJ (1997) Luminescence dating of loess from the northwest United States. *Quaternary Science Reviews* 16: 403–415; Busacca AJ and McDonald EV (1994) Regional sedimentation of late Quaternary loess on the Columbia Plateau: Sediment source areas and loess distribution patterns, regional geology of Washington State. *Washington Division of Geology and Earth Resources Bulletin* 80: 181–190.

greatly across the region; this reflects the different sources of material even over relatively short distances. In the Great Plains province, for example, studies have shown that silts from Tertiary White River Group outcrops in southern South Dakota and northern Nebraska form a major constituent of Peoria Loess in Nebraska (Aleinikoff et al., 1998). In neighboring eastern Colorado loess source material is derived from both the White River Group and glaciogenic valley sources draining the Front Range of Colorado (Aleinikoff et al., 1999). In the Central Lowland province, loess deposits located east of the Missouri and Mississippi Rivers are composed dominantly of glaciogenic source material, but some nonglaciogenic sources provide significant local loess contributions (Bettis et al., 2003). In the loess deposits of the lower Illinois and central Mississippi River Valleys, between 10 and 40% of the sediment is estimated to be derived from nonglaciogenic sources, based on the comparison of magnetic susceptibility, and silt and clay mineralogy (Grimley, 2000).

Loess deposits accumulated during glacial periods or stadials in the central United States, while paleosols formed during interglacials or interstadials. The cumelic nature of the Farndale Soil of the Central Lowland province and the Gilman Canyon Formation of the Great Plains province, suggests that loess accumulation continued throughout the interstadial but was sufficiently slow to allow pedogenesis to occur (Muhs et al., 2003). Most of the loess deposits preserved in the central United States were deposited during the last glacial period, when silt production rates from the LIS and from midcontinent nonglacial sources were extremely high. Thus, even where nonglacial sources were important, such as the Great Plains, loess deposition took place during the last glacial period. Equally significant, at this time vegetation conditions were also suitable for accumulation of loess in the central United States, with boreal forest present in the Central Lowland province (Baker et al., 1986, 1989) and parkland in the Great Plains province (Wells and Stewart, 1987); both have a high

Figure 10 Photograph of Holocene loess and underlying paleosol, possible last glacial loess, and highly cryoturbated, probable mid-Wisconsin paleosol at the Chena Hot Springs Road loess exposure, near Fairbanks Alaska (see [Muhs et al., 2003](#), for details). Photograph by D.R. Muhs.

dust-trapping potential. The importance of both production rates and the potential for accumulation in the development of loess deposits is illustrated for the central United States by consideration of the Holocene loess deposits of this region. In the Central Lowland province, loess accumulation potential is high because of the vegetation cover, but the production rate is extremely low; hence there is little or no Holocene loess preserved in the deposits of this area, although there may be small amounts of loess incorporated into the modern soils ([Mason and Jacobs, 1998](#)). Holocene loess production rates were somewhat higher in the Great Plains province, however, the accumulation potential was typically low, giving rise to modest Holocene (Bignell) loess deposits in this region ([Mason et al., 2003](#); [Muhs et al., 2003](#)) accumulating only where more effective dust-trapping topography and/or vegetation cover exists ([Mason et al., 1999](#)).

The timing of the deposition of loess in some areas of the Columbia Plateau province is inferred to be different from that for other loess deposits of North America and, indeed, the world ([Busacca et al., 2004](#)). Loess deposition rates are greatest in the Palouse region of eastern Washington. Here, the principal source of the loess is believed to be the flood sediments of proglacial Lake Missoula; the production and deposition rates of these loess deposits are therefore believed to peak late in the glacial cycle. In contrast to other locations, therefore, in the Palouse area pedogenesis occurred during glacial periods and stadials, while loess accumulation began toward the end of these cold periods and continued during interglacial periods and interstadials when the ice sheets retreated and the glacial outburst flood sediment sources were available ([McDonald and Busacca, 1998](#)). Thus, unlike the Great Plains region, loess in the Palouse region has a glaciogenic source, but the timing of deposition is not during the glacial maximum.

Geochemical tracing of the late Pleistocene Palouse loess demonstrates that it is derived from the glacial outburst flood

‘slackwater’ deposits ([Sweeney et al., 2002](#)). Further evidence that the slackwater deposits are the source of the Palouse loess is provided by the thinning of loess deposits with increasing distance from the slackwater deposits of south-central Washington and north-central Oregon ([Busacca and McDonald, 1994](#)). The loess deposits of the Snake River Plain are believed to be derived from the alluvial deposits of the Snake River as the deposits thin with increasing distance to the east and southeast of the river ([Busacca et al., 2004](#)). In contrast with the Palouse loess, the loess of the Snake River Plain is probably associated with deposition during glacial times and the paleosols are associated with warmer periods, in the same way as observed for the central United States and for many other locations worldwide, although more chronological studies are needed for this area.

The mineralogy and the major and trace element geochemistry of central Alaskan loess is distinctive from that of all other North American loess deposits ([Muhs et al., 2003](#)); it has unusually high iron oxide (Fe_2O_3) and aluminum oxide (Al_2O_3) contents, in spite of having a low clay content, and it also contains extremely low concentrations of carbonates. Alaskan loess is dominantly glaciogenic, with silt production being directly linked to glacial activity ([Muhs et al., 2003](#)). [Hallet et al. \(1996\)](#) demonstrated an order of magnitude increase in suspended sediment yields for drainage basins with more than 30% glacier cover compared to unglaciated Alaskan drainage basins. Clearly, in the past, silt production would have been expected to vary as ice cover varied. However, Alaska demonstrates the situation where conflicting conditions occur between maximizing silt production and maximizing the accumulation of loess. Contrary to the situation observed elsewhere in North America, [Muhs et al. \(2003\)](#) report that only moderate accumulation of loess occurred during the last glacial period in Alaska. Furthermore, extensive deposits of Holocene loess are found in Alaska, which in many locations are as thick or thicker than any potential last glacial deposits ([Muhs and Zárate, 2001](#)), challenging the classical view that the periods of maximum loess accumulation in Alaska correspond to glacial times.

A model of loess stratigraphic development in North America outlined by [Muhs et al. \(2003\)](#) proposes that there is a balance between factors influencing production and those affecting accumulation of loess. During times of potential maximum loess production in Alaska, that is, when the ice sheets and glaciers were most extensive, conditions for loess accumulation are at their least favorable because the herb-tundra vegetation which persisted during these cold conditions was an ineffective loess trap ([Begét, 1988](#)). This offers a potential explanation for the rather modest last glacial loess deposits observed in Alaska, even though loess production rates were probably extremely high ([Muhs et al., 2003](#)). Holocene loess production rates were not as high as those during glacial times, but the Holocene vegetation has been dominantly boreal forest whose much higher loess trapping potential has fostered the abundant thick Holocene loess deposits observed in Alaska ([Muhs et al., 2003](#)).

Paleoclimatic Implications

Due to their eolian transport mechanism, loess deposits provide one of the few direct records of atmospheric circulation,

preserving information regarding paleowinds. They can also suggest the past moisture balance of a region at the time of formation, and the amount of past vegetation cover (Muhs and Zárte, 2001). They also preserve floral and faunal paleoenvironmental indicators, along with other paleoclimatic proxies. Furthermore, they provide a record of the dust flux over time which is of increasing interest for models of climate change.

In the central United States, trends in Peoria Loess thickness (Figure 2), particle size, and also geochemistry, all indicate that the dominant direction of paleowinds was from the west or northwest (Mason, 2001; Muhs and Bettis, 2000). This finding is in direct contradiction with paleowind simulations from some atmospheric general circulation models (AGCMs) which predict prevailing easterly or northeasterly paleowinds resulting from a strong glacial anticyclone generated over the LIS during the Last Glacial Maximum (LGM; COHMAP Members, 1988). Similarly, climate model predictions of paleowind directions for the Pacific northwestern United States and Alaska and the neighboring Yukon Territory are also in disagreement with the observations from loess deposits. In contrast, however, recent observations of decreased loess accumulation rates across the Columbia Plateau during the LGM, arising due to suppression of the prevailing southwesterly dust-transporting winds, have been proposed as evidence supporting the modeled easterly wind anomaly south of the Cordilleran Ice Sheet predicted by AGCMs (Sweeney et al., 2004). The reasons for the discrepancies noted between modeled output and the geomorphologic evidence from various regions are not presently understood, and further investigation is required to resolve the inconsistencies that remain.

Interestingly, model simulations do not identify the Great Plains as being a significant source of dust during the last glacial period (Kohfeld and Harrison, 2000; Mahowald et al., 1999), yet the thickest last glacial loess deposits in the world are found here. The presence of nonglaciogenic loess in the Great Plains (Aleinikoff et al., 1998, 1999) indicates that factors other than simply glacial silt production are important for explaining loess origins during glacial periods. Possible factors of paleoclimatic significance include a sparse vegetation cover (e.g., a cool steppe vegetation) reflecting drier glacial climates (leading to the subsequent erosion of nonglacially derived silts and clays, for example, the White River Group and the Pierre Shale), lower temperatures, and stronger winds (e.g., Muhs et al., 1999). The loess of the Palouse region of the Columbia Plateau demonstrates that the accumulation of loess is not necessarily associated primarily with peak glacial activity; here, loess accumulation reaches its peak during Late Glacial and Holocene times when the supply of material is at its greatest.

The loess deposits of North America often contain proxy data for paleoclimatic conditions. The study of land snail species found in loess deposits, for instance, can yield important information regarding paleotemperature and paleoprecipitation, in addition to the vegetation type. For example, the discovery of extralimital northern or Cordilleran land snails in the Peoria Loess deposits of the Great Plains and Central Lowland indicates that colder conditions prevailed here in Late Glacial times (Rousseau and Kukla, 1994). Similarly, success has also been achieved in obtaining important information regarding the occurrence of forest or cool grassland

(‘C3’ plant communities) or of warm grassland (‘C4’ communities) from the carbon and oxygen isotope compositions of loess and minimally developed intercalated paleosols (e.g., Wang et al., 2000).

Loess deposits also provide a direct record of atmospheric dust flux, which may be used to assess the role of dust in climate change. The application of luminescence techniques to date the sediments that make up the loess deposits (rather than using radiocarbon dating of the paleosols that bracket the loess) has revealed that the accumulation rate varies over time. The high rates of loess deposition found in midcontinental North America (Bettis et al., 2003; Roberts et al., 2003) may have important implications for far-field (i.e., distant downwind) areas in terms of radiative and biogeochemical impacts. In spite of the observation that loess deposition decreases rapidly with increasing distance from the source, the fine-grained component of the loess may travel much further; this fine-grained component is more effective than coarser material in inducing radiative backscatter (Harrison et al., 2001), resulting in potential modification of the radiation budget even at distal locations where more modest loess thicknesses are found. Furthermore, fine-grained, far-traveled dust can also alter the atmospheric chemistry and affect the major biogeochemical cycles by providing an important source of nutrients to marine ecosystems (Harrison et al., 2001). Significant contributions of fine-grained (and little weathered) material to surface soils downwind of loess source areas in North America have also been reported (e.g., Mason and Jacobs, 1998).

While North American loess is a less significant present-day dust source than many other areas in terms of its potential effect on global climate (Kohfeld and Harrison, 2001), recent work suggests that it may have influenced past climate (Roberts et al., 2003). The role of dust in climate change is not well understood (Harrison and Kohfeld, 2001) but further study may prove it to be a significant factor, both for past and future climate change.

Introduction

The loess record of southern South America, the largest of the Southern Hemisphere, was originally reported in the nineteenth century under different names, among others by Charles Darwin in 1844. Its resemblance with the loess deposits of the Rhine valley was first noticed in 1866. Since then the term 'loess' has been loosely used in the literature to refer to the vast mantle of late Tertiary and Quaternary sediments of the Chaco-Pampean plain.

Loess-like deposits, loessoid deposits, reworked loess, loessic deposits, and secondary loess have been used to designate fine-grained, light-colored and massive sediments with the appearance of loess. Generally, loess-like and loessoid deposits are the terms most commonly found in the literature. Neotropical loess has been recently used to designate primary and reworked sediments of loessic character, distributed between latitudes 20° and 30° S. Also, the term tropical loess has been proposed to account for fine-grained surface deposits of massive appearance in northeastern Argentina, areas of southern Brazil, and northern Uruguay. These sediments, traditionally interpreted as *in situ* weathered byproducts from the underlying late Jurassic basaltic rocks, have been recently interpreted as a wide and extensive loess mantle that accumulated during the last glacial cycle. This hypothesis generated controversy and is presently under debate. Ongoing geochemical, mineralogical, and pedological analysis reinforce the *in situ* origin of the surface deposits.

During most of the twentieth century, research on South American loess was fragmentary and discontinuous. With few exceptions, a great number of contributions were focused on the stratigraphy and the fossil vertebrate content. A renewed interest began in the late 1980s specially driven by the necessity of testing global paleoclimatic models. Numerous studies were conducted particularly across the Pampean plain. The more detailed mapping, magnetostratigraphy, dating, paleopedological studies, and compositional analysis have substantially increased the understanding of the record. In recent years, detailed analysis substantially increased the knowledge of the loess–paleosol record of the mountain valley loess of Tucumán in northwestern Argentina. The Chaco loess is less known than the other two loess records, although regional aspects of its composition and geographical distribution have been reported.

Geographical Distribution

Loess distribution has always been associated with the extensive and heterogeneous Chaco-Pampean plain of southern South America, a region over 1 million km², covering most of northern central Argentina, western Uruguay, southern Brazil, western Paraguay, and southeastern Bolivia (Figure 1). This

generalization probably comes from the geographic distribution of loessoid deposits in Argentina and was later adopted in other studies, including not only loess but also sand dunes, sand mantles, and fine-grained deposits of noneolian origin. Subsequently, more detailed mapping across the Chaco-Pampean plain (Table 1) indicated a more restricted geographic distribution of loess; extensive areas of central Argentina are covered by eolian sands, while alluvial deposits are common in the northeast.

The Pampean Loess and Loess-Like Record

General Characteristics

The exposures of Pampean sediments are scarce and limited to quarries, road cuts, and river banks. The exceptions are the Chapadmalal sea cliffs near Mar del Plata and the Paraná River banks, 20–30 m thick and laterally continuous for several kilometers. Both of these unusually well-exposed sections have been the subject of numerous studies (Figure 2).

The Pampean sequences do not represent a continuous sedimentary record; stratigraphic discontinuities are indicated by several erosional unconformities while the rate and characteristics of the sediment supply varied through time. Loess is a secondary and minor component of the sedimentary sequences, being prevalent only during the last glacial cycle. Instead, loess-like deposits generated by the reworking of primary eolian sediments are dominant. Running water, mass-wasting processes on hill slopes, and deposition in swampy and lacustrine environments are thought to have been involved in the retransportation and resedimentation of primary loess. The reworking by aqueous transport agents resulted in several loess-like deposits including siltstones, clay siltstones, and sandy siltstones. They usually exhibit a general massive appearance or have poorly defined sedimentary structures frequently masked by pedogenesis and diagenesis.

Paleosols

The occurrence of pedogenic features is ubiquitous throughout the stratigraphic sequence of loess and loess-like deposits (Figure 3). The recognition and classification of paleosol soil horizons present several difficulties in field exposures. Paleosols were originally interpreted as truncated profiles with A horizons eroded by eolian and/or fluvial processes. Their identification has been mostly based on field morphological properties.

Detailed micromorphological analysis carried out at some stratigraphic intervals of the northern and southern Pampas show that pedogenesis was active throughout the sedimentation process resulting in accretionary soil profiles. Welding of pedological features on preexisting soil surfaces gives way to pedocomplexes. In addition, paleosols are not always discrete

Figure 1 Loess and loessoid distribution following several authors. Adapted from Frenguelli J (1955) *Loess y Limos pampeanos*. Ministerio de Educación de la Nación. Serie Técnica y Didáctica. Quaternary International* 17: 15–20.

entities, as their boundaries are sometimes obliterated by bioturbation, aqueous reworking, and grain size variation. Micromorphology also suggests that the balance between pedogenesis and sedimentation varied cyclically over time, with alternating phases of pedogenesis and intervals of much higher sedimentation rate. This pattern resulted in the identification of pedosedimentary cycles, thought to be ultimately driven by climatic changes.

Carbonate Accumulations

Carbonate accumulations, known locally as ‘tosca,’ constitute a very common feature of the loess and loess-like deposits of

the southern and northern Pampas. Their origin has been attributed to both pedogenesis and groundwater processes. Carbonate accumulations exhibit very diverse morphologies including carbonate-cemented sedimentary layers, nodules, and concretions ranging from millimeters to half a meter in size, as well as veins (Figure 4). Carbonate rhizoconcretions are also present, associated with paleosol horizons.

Calcrete crusts are another common and characteristic feature of the southern Pampas sequences. In addition, crusts are developed on the surfaces of late Miocene and Pleistocene loess-like deposits. They exhibit complex morphologies, resulting from multiple episodes of brecciation, dissolution, and reprecipitation. The thickness varies from a few centimeters

Table 1 Summarized characteristics of the loess record in the Pampas, Chaco and the mountain valleys of Tucumán

Area	General knowledge	Sedimentary record	Stratigraphic record
Pampean loess record	Numerous studies on stratigraphy, vertebrate fossil remains, paleopedology, magnetostratigraphy, and geochronology: several numerical dates by ^{14}C , TL, OSL, Ar/Ar	Discontinuous sedimentary record Loessoid deposits dominant component Loess prevalent during last glaciation forming a continuous apron	late Miocene (~10 Ma) to Holocene record
Chaco loess record	Not known in detail. Information available on areal distribution and partially on composition, very few dates (^{14}C)	Loess covering several areas of the plain	Last Glacial–Holocene loess
Northwest Argentina, Tucumán Mountain valley loess record	Studies performed since the 1980s; several recent papers on pedostratigraphy, micromorphology, ^{14}C , and OSL dates, geochemistry, magnetostratigraphy	Continuous stratigraphic loess–paleosol record. High resolution	Mid-Pleistocene to Holocene loess–paleosol record

Figure 2 Exposures of the Pampean loess and loess-like record. (a) Chapadmalal sea cliffs south of Mar del Plata. (b) late Miocene and Pliocene loess deposits at a river bank in Ventania range. (c) Gorina quarry in La Plata. (d) Outcrop along the left margin of the Paraná River in Baradero, northern Pampas.

to more than 2 m, depending on the relative age of the geomorphic surfaces where they are present. No numerical ages have been obtained.

Vertebrate Fossil Content

The abundant vertebrate fossil remains recovered from the late Cenozoic loess and loess-like deposits have been the subject

of numerous studies, dealing particularly with their taxonomy and biostratigraphic implications. Fossil assemblages consist of autochthonous endemic groups (including edentates, litopterns, notoungulates, and marsupials) and Holarctic immigrants (including carnivores, cervids, camelids, and horses) which gradually migrated to South America at different stages. A major faunal turnover, whose origin is still debated, is recorded in the late Pliocene loess-like deposits of Chapadmalal.

Figure 3 Field exposures of paleosols. (a) Truncated paleosol of the mid-Pleistocene developed on loess deposits, Gorina quarry, near La Plata. (b) late Pliocene loess–paleosol sequence at Chapadmalal, Bt horizons more eroded and with darker colors.

Fossil assemblages have been grouped into different land mammal ages or stages–ages based on their relative degree of evolution (Table 2). All the type localities of the late Miocene to Pleistocene stage–ages (except for the Huayquerian, situated in the Andean piedmont), are located in the southern and northern Pampas of Buenos Aires province.

In addition to fossil bones, loess and loess-like deposits exhibit striking mammal bioturbation features represented by burrows and caves of variable sizes (Figure 5). The smaller burrows, with diameters of less than 20 cm, were formed by fossil rodents. Large burrows, with diameters between 0.80 and 1.80 m, are also common. Their morphological characteristics and the occurrence of claw marks on the walls and roofs, along with biomechanical analysis of fossil limbs, suggest that the mylodontid sloths *Scelidotherium* and *Glossotherium* were the probable builders of these burrows.

Prior to the initiation of magnetostratigraphic studies, fossil assemblages were the only tools available to assign relative ages and correlate isolated and distant loess sections across the Pampean plain. This resulted in a regional chronostratigraphic scheme of the loess and loess-like record.

Impact Glasses

A remarkable feature of the loess and loess-like deposits of South America is the occurrence of vesicular and glassy fragments, ranging in size from a few millimeters up to clusters 1–2 m in diameter. These fragments, known as ‘escorias’ are found at localities of the southern Pampas and in Río Cuarto (northern Pampas; Figure 6). In stratigraphic sections, they form horizons characterized by a relatively high concentration of fragments of different sizes and can be traced laterally for several hundreds of meters or even kilometers at some localities.

Reworked escorias fragments from these main horizons are commonly embedded in younger fluvial deposits; some secondary reworking is due to vertebrate bioturbation. Their genesis, debated for decades, had been previously attributed to natural fires, volcanic and igneous activity, and even *in situ* diagenetic processes. However, recent studies of the geochemical and petrographic character of escorias show clear signatures of an impact origin. High-resolution argon-40/argon-39 ($^{40}\text{Ar}/^{39}\text{Ar}$) dating of the fresher-appearing glass indicates the occurrence of five impact events in the southern Pampas recorded at sections cropping out in Chapadmalal, Centinela del Mar (two events), Bahía Blanca, and Chasicó (Table 3). In Río Cuarto, impact glasses have been found scattered on exhumed surfaces with relative age, fission track, and $^{40}\text{Ar}/^{39}\text{Ar}$ dating indicating the presence of at least two additional Holocene and Pleistocene impact events.

Magnetostratigraphy

Magnetostratigraphic analysis has been performed on several sections of loess and loess-like deposits of the northern Pampas in the vicinity of Buenos Aires and the Chapadmalal sea cliffs in the southern Pampas (Table 4).

When no numerical ages are available for chronology the magnetostratigraphic interpretations, however, are constrained by the stratigraphic discontinuity and the common lateral facial changes. As a result, several alternative interpretations have been proposed at some sections. The magnetostratigraphy of Chapadmalal suggests an early Gauss-to-Gilbert magnetic age (>3.15 Ma) for the lowermost levels supported by later studies indicating ages close to 4 Ma. The sequence is completed by a discontinuous record of loess-like deposits accumulated during the Gauss–Matuyama and Brunhes magnetic ages.

In the northern Pampas, the paleomagnetic analysis suggests a Matuyama age younger than 2 Ma for the oldest levels cropping out at the bottom of several quarries. The Brunhes–Matuyama boundary is identified at several sections at a variable depth of 5–10 m from the surface. The onset of the Brunhes chron is thought to be characterized by a new pulse of loessic sedimentation in coincidence with an increase in the Andean volcanic activity and a change to drier and colder climatic conditions.

Magnetic Susceptibility

Near the city of Buenos Aires in the northern Pampas, low susceptibility is recorded in paleosols and higher susceptibility in loess layers. This contrasts with the loess–paleosol record of

Figure 4 Morphologies of carbonate accumulations. (a) Calcrete crusts in late Pliocene and Pleistocene loess-like deposits at a Chapadmalal quarry. (b) Calcrete crust on top of Pliocene loess deposits in Tandilia. (c) Veins, nodular and massive calcium carbonate layers eroded by paleochannels, early Pleistocene loess-like deposits at Chapadmalal. (d) Rhizoconcretions and reticulate pattern of carbonate stringers associated with a paleosol level, Chapadmalal.

Table 2 Stages–ages (land mammal ages) and type localities in the Pampean region (adapted from Cione and Tonni (2001), and references therein)

Area	Type locality	Stages–ages (land mammal ages)	Sedimentary deposits
Northern Pampas of Buenos Aires province	Stratigraphic sections located in the surroundings of Buenos Aires city and La Plata	Platan	Lacustrine and fluvial facies – loess
		Lujanian	Fluvial deposits – loess
		Bonaerian	Loess–loessoid deposits
Southern Pampas of Buenos Aires province	Chapadmalal sea cliffs	Ensenadan	Loessoid deposits of paludal and fluvial environments
		Marplatan	Loessoid deposits of fluvial environments
	Chapadmalal sea cliffs	Chapadmalan	Loessoid deposits of hill slopes and of fluvial environments
	Monte Hermoso	Montehermosan	Loessoid deposits of fluvial environments
	Arroyo Chasicó in southern Buenos Aires	Chasicooan	Very fine sandstones and loessoid deposits siltstones of fluvial and paludal environments

China, but is similar to what has been reported for Alaska. Magnetic susceptibility changes have been interpreted as evidence of alternating periods of wet and dry conditions. Low susceptibility values are reported in calcrete layers and reduced sediments and high values in the B horizons. The magnetic

mineralogy is dominated by multidomain magnetite, behavior attributable to fine silt-sized particles most likely of detrital origin. Diagenetic processes and past climatic conditions have been considered as possible controlling factors of magnetic susceptibility. The magnetic signals of late Pleistocene and

Figure 5 Bioturbation structures. (a) Rodent burrow in Pliocene loess at the Chapadmalal sea cliffs. (b) Cave excavated in loess-like deposits north of Mar del Plata.

Figure 6 Fragment of impact glass (escoria) found in late Pliocene loessoid deposits of the southern Pampas.

Holocene alluvial and eolian deposits at two Pampean fluvial environments of Buenos Aires suggest that the genesis of a high-coercive fraction in loessic sediments is tentatively associated with dissolution. Pedogenesis is considered the cause of magnetic signal variations in paleosols showing extensive dissolution of detrital ferrimagnetic minerals. High-coercivity minerals are thought to indicate climatic conditions characterized by a dry season.

Table 3 Numerical ages of impact glasses

Localities	Host sediments	Glass age
Rio Cuarto northern Pampas	Surface material	4–10 ka 2.3 ± 1.6 ka 6 ± 2 ka 570 ± 100 ka 114 ± 26 ka
Centinela del Mar southern Pampas	Loessoid deposits of fluvial environment	230 ± 30 ka 445 ± 21 ka
Chapadmalal sea cliffs (Mar del Plata) southern Pampas	Loess and loessoid deposits	3.27 ± 0.08 Ma
Bahia Blanca southern Pampas	Loessoid deposits	5.33 ± 0.05 Ma
Chasicó southern Pampas	Loessoid deposits and fine sandstones	9.23 ± 0.09 Ma

The Mountain Valley Loess of Tucumán

Loess–paleosol sections over 40 m thick have been reported at various sites in a mountain valley of Sierras Pampeanas in Tucumán province (Figure 7). The sections, located at altitudes between 2300 and 2500 m above sea level, are exposed along gully and river walls of the Tafi del Valle intramountain basin, a closed basin that acted as a sediment trap to eolian dust throughout the Quaternary.

Twenty-eight discrete paleosols consisting of Bw, Bt, and C horizons were recognized at the La Mesada section on the basis of morphological properties (color, structure, texture, and clay coating). Detailed micromorphological analysis carried out at two stratigraphic intervals of La Mesada permitted the identification of a series of three main pedosedimentary stages (Table 5), interpretation probably applicable to the rest of the sequence. The pedosedimentary stages include an interval of accretionary pedogenesis, followed by a relatively stable surface characterized by the dominance of pedogenic process and a return to accretionary pedogenesis. Also, a cyclical pedosedimentary history is inferred at the 45-m-thick loess–paleosol sequence of El Lambadero on the basis of field properties, magnetic susceptibility, particle size, calcium carbonate content, and soil micromorphology.

Magnetostratigraphy, geochemistry, and micromorphology were carried out at the 50-m-thick Las Carreras loess–paleosol sequence. The succession comprises 32 paleosols classified as Luvisols and (Luvic) Kastanozems. Carbonate leaching and reprecipitation, soil aggregation, and clay translocation are, among others, the major pedogenic processes involved in paleosol development. It is considered a quasicontinuous and complete continental record of climatic changes and environmental conditions in subtropical South America. The paleomagnetic analysis indicates a Matuyama magnetic age for the lower 15 m with the Brunhes–Matuyama boundary found at a depth of 26.7 m. A minimum age of 1.15 Ma is assigned to the onset of loess sedimentation. The relative maxima of magnetic susceptibility correspond mainly with loess and relative

Table 4 Location of the main magnetostratigraphic sections studied in the Pampean loess sequences

Area	Localities	Magnetostratigraphy
Mountain valleys of Tucumán	Las Carreras section	Brunhes
Northern Pampas	Buenos Aires city: three magnetostratigraphic sections (building excavations)	Matuyama (<1.15 Ma)
		Brunhes
	Baradero: two magnetostratigraphic sections	Matuyama (upper part), Jaramillo subchron recorded. Exposed lower level >1.5 Ma
		Brunhes
Southern Pampas	La Plata: three main magnetostratigraphic sections in building excavations and quarries	Matuyama
		Brunhes
	Chapadmalal sea cliffs, Mar del Plata: four magnetostratigraphic sections	Matuyama (upper part), subchron Jaramillo recorded. Exposed lower levels >1.5 Ma
		Brunhes
		Matuyama
		Gauss
		Gilbert (lower levels exposed >4 Ma)

minima with paleosols following a pattern similar to the Pampean loess–paleosol sequences. High susceptibility values were found associated with the presence of organic matter in both fossil and the modern Ah soil horizons. The paleoenvironmental or sedimentological significance of magnetic susceptibility signals, however, remains unclear and more studies are needed to explore the relation of the magnetic properties and lithology.

The Last Glacial Loess Record

Geographic Distribution

The eolian sediments of the last glacial cycle form a very extensive and continuous apron that blankets the landscape of the Pampean plain as well as extensive areas of the Chaco plain. The deposits constitute the parent material of the present cultivated soils (Figure 8). Small patches of loess are also found along the proximal Andean piedmont and intramountain valleys of Sierras Pampeanas (Figure 1).

Grain Size Zonation

Across the Pampean plain eolian deposits exhibit a regional west-southwest to east-northeast grain size zonation.

Figure 7 Mountain loess from Tafi del Valle, Tucumán. (a) Panoramic view of the upper part of the loess–paleosol sequence near La Mesada. (b) General view of El Lambadero section. Photos courtesy of Rob Kemp.

Loess is surrounded by a large sand dune field west and south-southwestward which extends along the distal eastern Andean piedmont, covering most of the wide valley of the Bermejo–Desaguadero–Salado fluvial system, as well as the floodplains and fan environments of the San Juan, Mendoza, Tunuyán, Diamante, and Atuel rivers. The sand dune fields and sand mantles extend eastward to around 150 km west of Buenos Aires, including large-scale dunes trending north-northeastward–south-southwestward. Southward, the sandy eolian facies continue along the Colorado and Negro fluvial valleys surrounding the southern Pampas where sandy deposits grade into loessial sands and sandy loess facies (Figure 9).

Local topographic factors promote the deposition of loess on the surface of structural plains of La Pampa province (Figure 9) and along the proximal eastern piedmont and intramountain basins of Sierras Pampeanas of Córdoba and San Luis.

In the Chaco plain, the loess cover is more discontinuous, alternating with alluvial deposits. Sand dunes composed of fine sands of dominantly quartz composition are reported in the Bolivia–Paraguay low plain.

Mineralogical Composition

In the southern Pampas, sandy loess is mostly volcanoclastic consisting of andesitic plagioclase, hornblende, pyroxene, volcanic glass shards, and quartz grains. Volcanic rock fragments

Table 5 Main characteristics of Tucumán mountain valley paleosols

Sections and thickness (m)	Number of paleosols	Paleosol characteristics
La Mesada (1, 2) (42 m)	28	(1) Bw and Bt horizons interbedded with loess (C horizons) (2) Micromorphology suggests three pedosedimentary stages: accretionary pedogenesis, relative stable surface, and return to accretionary pedogenesis
El Lamedero (2) (45 m)	One in the uppermost 6 m profile. Two in the lowermost 4.5 m profile	Bt, BC, and C horizons identified pedocomplex in the upper section; three pedosedimentary stages cyclical development with four pedosedimentary stages
Las Carreras (3) (50 m)	32	Bt, BC horizons, A horizons mostly present but difficult to identify Main pedogenic processes: carbonate leaching and reprecipitation, pedogenic formation and translocation of clay and organic matter

are very common. Particles are very fresh and usually well rounded (volcanic rock fragments, magnetite, pyroxenes) or subrounded to subangular (clinopyroxenes, orthoclase, plagioclase). Illite, poor in potassium, is the dominant clay mineral in Pleistocene–Holocene loess sequences, while smectite and kaolinite are secondary components (Table 6).

In the northern Pampas of Buenos Aires, the mineralogical composition of loess varies throughout the sections. It is predominantly composed of volcanoclastic material (glass shards and plagioclases); the sand fraction includes metamorphic rock fragments (gneisses, migmatites, etc.). Illite and smectite are the predominant clay minerals (Table 6). In southern Santa Fé, the last glacial loess is composed of volcanoclastic material as well as a secondary percentage of metamorphic and igneous rock. Quartz is a dominant component of Chaco loess.

Geochemistry and Isotopic Composition

The isotopic ratios (strontium-87/strontium-86 ($^{87}\text{Sr}/^{86}\text{Sr}$), neodymium-143/neodymium-144 ($^{143}\text{Nd}/^{144}\text{Nd}$)) of loess samples covering the time interval of ca. 10–150 ka from four localities of the Pampas (Hipodromo, Gorina, Baradero, and Lozada) and one locality from the mountain valleys of Tucumán (Lambadero) are characterized by a broad range of $^{87}\text{Sr}/^{86}\text{Sr}$ values and restricted $^{143}\text{Nd}/^{144}\text{Nd}$ ratios (0.5123–0.5126). A significant geographic variability exists and individual sites show less isotopic variability. Chondrite-normalized rare-Earth element (REE) patterns are generally consistent with loess from other regions and characterized by light REE enriched patterns, flat heavy REE trends, and negative europium anomalies.

Geochronology

Some radiocarbon ages together with a few thermoluminescence (TL) ages were first used to determine the chronology of

loess deposition in South America. A correlation with the marine isotopic stage stratigraphy was proposed for the northern Pampas of Santa Fé. New optically stimulated luminescence (OSL) analyses have provided numerical ages of some representative Pampean loess–paleosol sections and La Mesada and El Lambadero sections in the Tucumán mountain valleys. The intervals of dominant soil formation and periods of increasing depositional rates identified on the basis of detailed micromorphological analysis were chronologically bracketed and tentatively correlated with the marine isotope stratigraphy. Among other results, the OSL chronology suggests different deposition rates across the region with loess accumulating until the mid-Holocene in the western part of the northern Pampas. Discrepancies have arisen with OSL ages that suggest older ages than previously indicated by both radiocarbon and TL chronologies. At La Mesada, OSL ages ranging from 150 to 195 ka BP are much older than those indicated by the radiocarbon chronology (<30 ka BP). Consistent with this, the magnetostratigraphy in another nearby section (Las Carreras) suggests much older ages (Table 7).

Provenance of Loess Deposits

The mineralogy and geochemistry of loess in South America indicates that the Andes Cordillera, Sierras Pampeanas of Córdoba, and San Luis, and the Paraná River basin have been the most important source areas, with their relative inputs varying across the region (Figure 10). The isotopic data are consistent with multiple loess sources with a majority of particles being derived from the Andes. Discrete tephra layers, along high percentages of fresh volcanic shards within the loess suggest the direct input of Andean volcanic eruptions coming from the Central Volcanic Zone and the Southern Volcanic Zone. These two volcanic districts seem to have had a major

Table 6 Geographic distribution, mineralogical composition, source areas, and inferred wind systems of last glacial loess (adapted from Zárate, 2003 and references therein). Source areas of mountain valleys in Tucumán according to Smith et al. (2003) and Schellenberger and Veit (2006)

<i>Area</i>	<i>Eolian deposit</i>	<i>Mineralogical composition</i>	<i>Source area</i>	<i>Inferred transport-wind systems</i>

Mountain valleys of Tucumán	Loess	Volcaniclastic composition dominant	Western Andean source (Chilean altiplano) Local sources. Tephra from CVZ	Northerly winds Westerly winds
Northern Pampas (Pampa Ondulada of Buenos Aires, southern Santa Fé, Córdoba)	Loess	Volcaniclastic composition dominant	Andes Cordillera, Sierras Pampeanas, Paraná basin, Uruguayan shield. Tephra from CVZ and the SVZ	South-southwesterly winds
	Clayey loess	Secondary amount of metamorphic and igneous rocks		(?)North/northeasterly winds (?)Tropospheric winds from the Puna/Altiplano
Northern Pampas (Pampa Deprimida)	Sandy loess (WSW) grading to typical loess (ENE)	Volcaniclastic composition dominant ENE area: not determined	Northern Patagonia (late Tertiary volcaniclastic sediments) Andes Cordillera (34–38° S)	South-southwesterly winds Holocene: westerly winds
Southern Pampas	Sand mantles	Volcaniclastic (<quartzitic and metamorphic rocks)	Sierras Pampeanas (?). Tephra from SVZ and CVZ (?) Northern Patagonia (late Tertiary volcaniclastic sediments)	South-southwesterly winds
	Loessial sands. Sandy loess. Clayey loess (<)		Andes (34–38° S). Tandilia and Ventania. Tephra from SVZ	Holocene: westerly winds

Table 7 Chronology proposed for the loess–paleosol sections studied in the mountain valleys of Tucumán according to Zinck and Sayago (1999), Zinck and Sayago (2001), Kemp et al. (2003, 2004), and Schellenberger et al. (2003)

<i>Sections</i>	<i>¹⁴C dates</i>	<i>OSL dates</i>	<i>Magnetostratigraphy</i>
La Mesada	Four dates between ~5–42 m of depth: age range from ca. 17.5 to 27.5 ka	Three dates between 35 and 42 m of depth: ages >152 ka	–
El Lamedero	–	Upper 6.1 m: 33–96 ka and lowermost 4.7 m: >165 ka	–
Las Carreras	–	–	Brunhes–Matuyama including Jaramillo subchron and Kamikatsura event

influence on the different compositions of loess in different regions of South America. The volcanoes of the Puna plateau probably were the main source of loess in the Chaco region and some of the northern Pampas tephras. The volcanic eruptions of the Southern Volcanic Zone are more significant as a loess source material in the southern Pampas.

The loess and sand deposits of the southern Pampas are mostly derived from Andean pyroclastic and volcanic rocks. Only a minor and localized contribution from the mountain ranges of southern Buenos Aires is present. In the northern Pampas, Andean volcaniclastic material is dominant in Santa Fé and northern Buenos Aires province. The Sierras Pampeanas of Córdoba and San Luis constitute a secondary source area, providing particles of metamorphic and igneous rocks and traces of kaolinite. In addition, the

Paraná River basin contributed as a secondary source. The metamorphic outcrops located on the Uruguayan margin of the Río de la Plata might be another potential secondary source area.

The isotopic signatures suggest that the Chilean Altiplano was the source area of the mountain valley loess of Tucumán. Presumably direct ash falls and local dust sources were secondary contributors.

Paleoclimatic Significance of the Loess Record

Wind Systems

Two regional-scale sedimentological models have been proposed to explain loess origins in South America. The ‘Chaco

Figure 10 Source areas of loess and eolian sands. Adapted from Zárate M (2003) The Loess record of Southern South America. *Quaternary Science Reviews* 22: 1987–2006.

model' and the 'Pampean model' were formulated by Iriondo (1997) to illustrate source areas, transport pathways, and depositional areas for loess of the northern and southern regions, respectively. The Chaco model suggests that during last glacial period, northerly wind systems deflated the floodplains of the Parapetí, Pilcomayo, and Bermejo rivers, depositing the Chaco loess. The loess of the mountain valleys of Tucumán is now considered to be part of the Chaco model.

The Pampean model explains the loess record further south. Particles were deflated from the floodplains of the Colorado and Negro rivers, and the Desaguadero fluvial system, a tributary of the Colorado (Figure 9). The westerly and south-westerly transport directions inferred from geomorphological,

sedimentological, and geochemical evidences agree with westerly paleowind simulations derived from climate models.

South American Source of Antarctic Dust

A South American origin has been attributed to dust found in Antarctic ice cores. In general, the isotopic ratios of the eolian dust records from the Epica-Dome C and Vostok ice cores suggest that the Pampas, Patagonia, and possibly the exposed continental shelf of Argentina were the dominant sources of Antarctic dust. Detailed studies are needed to find out which of these regions were the main contributors of Antarctic dust.

Conclusions

Information is still lacking from several areas across the region, particularly the Chaco plain and the Andean mountain valleys north and south of Tucumán whereas recently proposed chronologies need to be tested in order to understand fully the paleoclimatic significance of the loess record. Many of the studies have been carried out in the Pampean plain. Here, the late Miocene to Holocene record is a complex stratigraphic succession mostly composed of loess-like deposits, numerous welded paleosols, and several erosional unconformities. The paleoenvironmental and paleoclimatic interpretations derived from the record should be examined carefully considering local and regional factors of controls. At a regional scale, loess deposits become a dominant component of the sequences during the last glacial period. Differences in sedimentation rates, sediment supplies, and soil development reflect heterogeneous environmental conditions through time across the vast Chaco-Pampean plain. To date, the apparently continuous and complete mountain valley loess–paleosol sequence of Tucumán, in north-western Argentina, dating back to around 1.15 Ma, is the most promising continental proxy record of paleoenvironmental and paleoclimatic conditions of southern South America.

This article is reproduced from the previous edition, volume 2, pp. 1480–1491, © 2007, Elsevier B.V.

Thermoluminescence (TL) dating is based on the fact that natural minerals can absorb and store ionizing energy. If a mineral is heated to a sufficiently high temperature, some of the stored energy is released in the form of light called TL; a subsequent exposure to heat will not result in more TL being emitted unless the mineral is first allowed to absorb more ionizing energy. Exposure to light (e.g., natural sunlight) will also cause some of this stored energy to be lost.

In the natural environment, the energy absorbed by a mineral mainly comes from radiation emitted from radioisotopes within the mineral grain, from its immediate surroundings, and from cosmic rays. The rate at which a dose of radiation energy is absorbed by a mineral (the dose rate) is therefore proportional to the concentrations of radioisotopes and to the intensity of cosmic rays at the sample site. Simply stated, for a given mineral sample, what is needed to determine a TL age is (1) the laboratory dose of radiation that produces the same intensity of TL as did the environmental radiation dose (called the equivalent dose) and (2) a measure of the environmental dose rate. The TL age is simply the equivalent dose divided by the dose rate. TL dating therefore gives the time elapsed since mineral grains were last exposed to sufficient heat or sunlight.

TL dating was developed in the early 1960s as a means of dating fired pottery (Aitken, 1985; Aitken et al., 1964, 1968; Roberts, 1997), but the technique was later modified so that it also could be used to date the last time that sediments were exposed to sunlight. TL dating is part of a family of chronological techniques collectively referred to as trapped charge dating. Related methods include electron spin resonance dating, optical dating, and radioluminescence dating (Krbetschek et al., 2000).

Following the seminal publication by Daniels et al. (1953) on the potential of using TL in geological and archaeological research, TL-dating techniques that could be used to date unheated sediments were developed independently in the mid- to late 1960s in the former Soviet Union and in North America. Historical reviews can be found in Dreimanis et al. (1978), Wintle and Huntley (1982), Aitken (1985), and Lian and

Roberts (2006). TL dating is now a well-established method with an established age range of approximately 500–500,000 years, but in special cases ages as old as 1 Ma have been calculated. Because Quaternary geoscientists are mainly concerned with natural sedimentary environments, only the TL-dating techniques relevant to this application are discussed in this article. Discussions of the methods relevant to archaeological materials (e.g., fired pottery, hearthstones, artificial glass, and slag) can be found in Fleming (1979), Aitken (1985, 1990), Roberts (1997), Feathers (1997), and Wagner (1998), although the differences between the methods are not major.

Mechanism Responsible for TL

TL refers to the light emitted by matter in response to heat. It is not to be confused with incandescence, which is the light emitted from red-hot coals or a light bulb filament. In the case of TL, further heating will not result in more light being emitted, unless the material is first allowed to absorb ionizing energy. The physical models used to explain the TL phenomena are complex and not fully understood; a comprehensive account of the physics behind the mechanism is provided by McKeever (1985), whereas concise, and varied, accounts relevant to dating can be found in Aitken (1985), Wintle (1997), McKeever and Chen (1997), and Wagner (1998).

Crystals, such as those comprising natural minerals, are not perfect and contain impurities and structural defects, some of which are attractive to electrons that have been freed from their normal sites in the valence bands of atoms. Free electrons are produced when atoms absorb ionizing radiation that occurs in the natural environment.

Free electrons may subsequently be trapped at impurity or structural defect sites (traps) for a time that depends on the strength, or thermal lifetime, of the particular trap. At environmental temperatures (~20 °C), traps with long thermal lifetimes (sometimes referred to as deep traps) may hold electrons for

millions of years or more, whereas traps with short thermal lifetimes (shallow traps) may hold electrons for only a few days or less. In any given mineral grain, there are many different kinds of defects and impurities; many of these can act as electron traps, and these, in turn, all have different thermal lifetimes.

When a mineral grain is exposed to an external source of energy (e.g., heat or light), an electron in a trap may acquire enough energy to escape from it. Once evicted, an electron will travel around the crystal lattice until it eventually becomes retrapped or comes across another kind of site attractive to electrons referred to as a recombination center; this process of eviction and recombination is nearly instantaneous. When an electron encounters a recombination center, it combines with the atom there and excess energy is given off either as heat (lattice vibrations or phonons) or as luminescence (e.g., TL); in the latter case, the process is referred to as radiative recombination. If irradiation continues, electron traps will continue to fill until a further dose of radiation results in no more TL being measured. This condition is referred to as saturation.

All electron traps can be emptied if a mineral grain is exposed to sufficient heat, but only some of these traps can be emptied by exposure to light. Of the light-sensitive traps responsible for TL, some can easily be emptied by a brief exposure to sunlight exposure, but there are others for which a much longer sunlight exposure is needed. During laboratory heating, both incandescence and TL are emitted, but these are separated using infrared and red absorbing optical filters so that it is mainly the violet or ultraviolet TL that is being recorded.

TL Dating

As mentioned previously, to calculate a TL age requires an estimate of the equivalent dose and measurement of the environmental dose rate. These are discussed in turn.

Estimating the Equivalent Dose

There are several TL-dating procedures available for estimating the equivalent dose. Detailed discussions with various emphases can be found in, for example, Wintle and Huntley (1982), Aitken (1985), Singhvi and Wagner (1986), Berger (1988a,b, 1995), Forman (1989), Lian and Huntley (2001), and Lian and Roberts (2006). Of the TL-dating procedures available, the best established are the additive dose, total bleach, partial bleach (sometimes called the *R*-gamma or *R*-beta method, depending on whether gamma or beta radiation is used), and the regeneration methods. All these methods require that 20–50 aliquots of a sample be prepared. These aliquots are then given various laboratory radiation doses, in some cases several are exposed to light (i.e., they are bleached for a specific duration under laboratory light or natural sunlight), and then their TL is measured using an apparatus such as that shown in Figure 1. These data are used to model the way a sample's TL responds to absorbed radiation dose. From this dose-response model, the radiation dose the sample had absorbed since it was last heated or exposed to sunlight is estimated. This absorbed dose estimate is commonly referred to as the equivalent dose because it is found using the dose-response constructed using either beta particles or gamma rays from laboratory radiation sources, whereas in the environment, the

dose that the sample absorbed has come from alpha, beta, gamma, and cosmic ray radiation. Equivalent dose is commonly denoted by ED, D_{eq} , or D_{eqr} , and it is sometimes referred to loosely (and incorrectly) as paleodose.

Of the techniques used to estimate the equivalent dose, the additive dose method is the simplest. It is used in cases in which mineral sediment has been exposed to enough heat to empty all the relevant electron traps. The dose-response is constructed by giving several aliquots of the prepared sample various radiation doses while leaving some of them undosed; these latter aliquots are referred to as naturals (commonly denoted by *N*). TL from all the aliquots is recorded as a function of temperature, and data sets consisting of TL intensity as a function of laboratory dose are determined for successively increasing temperatures (e.g., 200–500 °C). For each data set, a curve is fitted and extrapolated to where it intercepts the dose axis. When a temperature range associated with thermally stable traps has been reached, the dose axis-intercept values will be constant, forming what is commonly referred to as a TL plateau. The equivalent dose is usually taken to be the average value of the dose-intercept values that fall within the plateau. If the dose-intercept values do not form a plateau, then something is amiss and an equivalent dose cannot be determined from them. Achieving a plateau in the dose-response versus temperature data is therefore a necessary condition for providing a TL age. An example of the additive dose technique is shown in Figure 2.

In cases in which the event to be dated is the last exposure to extended sunlight, the total bleach method is often used (Singhvi et al., 1982; Wintle and Huntley, 1979). The concept is that the measured TL intensity, *I*, can be considered as being the sum of two components, I_0 and I_d . I_0 is the TL intensity that would have been measured had the sediment sample been collected immediately after burial, which results only from electrons in light-insensitive traps, whereas I_d is the TL intensity resulting from the environmental radiation dose absorbed since the sample was buried. A clear-cut division of the traps into two such types probably does not exist in reality, although in practice it appears to be a good approximation. The total bleach method involves extrapolating the dose-response curve to the TL intensity value of a natural aliquot that has received an extended exposure to sunlight of a duration and spectrum similar to that which it would have received in nature (Figure 3(a)).

As mentioned previously, the relationship between I_0 and I_d is an approximation. In reality, there are electron traps with a wide range of sensitivities to light, and therefore, it can be expected that there are cases for which some of the relevant traps remain full even after prolonged sunlight exposure. Moreover, there is concern that the extended sunlight exposure used in the total bleach method may result in TL sensitivity change and other unwanted effects. These problems are taken into account using the partial bleach method (Wintle and Huntley, 1980; Figure 3(b)). With the partial bleach method, the TL reduction caused by a relatively brief, and usually spectrally restricted, light exposure is measured as a function of laboratory radiation dose, with the goal that only the light-insensitive traps are sampled during TL measurement. These data are then extrapolated to zero reduction to find the dose axis intercept. The way this is done in practice is to construct a

Figure 1 Schematic diagram of an apparatus (glow oven) designed to measure and record TL from sediments. The apparatus is a basic system designed to measure one sample aliquot at a time. More advanced systems, which are automated, can measure many aliquots in a run and can perform irradiations onboard. For the basic apparatus shown, a sediment sample is mounted on a ~1-cm-diameter aluminum or stainless-steel disk, which is in turn placed on the nichrome heater plate. The sample disk is commonly secured with a thermal compound paste so that there will be good thermal contact between it and the heater plate. The glow oven chamber is then evacuated, and the atmosphere is replaced with an inert gas, such as argon or nitrogen. The chamber needs to be evacuated to avoid the measurement of spurious TL, and an inert gas atmosphere is needed in the chamber to ensure good thermal contact between the disk, the sample grains, and the heater plate. The nichrome plate is heated at a constant rate by an electrical current, and TL photons are emitted from the sample as a consequence. The top of the chamber is transparent, allowing photons to pass from the sample through the light guide, which contains optical filters, to the photocathode of the photomultiplier tube (detector), where they result in the production of electrons (photoelectrons). The number of electrons that result from this process depends on the quantum efficiency of the photocathode, which typically is between 0% and ~25%, depending on the wavelength (energy) of the incident photons. Electrons produced at the photocathode are accelerated between several dynodes, each step resulting in the production of more electrons. For a typical photomultiplier tube, one electron at the photocathode will result in millions of electrons reaching the anode. The other equipment shown in the diagram is used to measure and control the heating rate (thermocouple) and to amplify and modify the pulses at the photomultiplier tube anode so that they can be recorded by the computer. The output example shown consists of two glow curves – plots of TL intensity (photon counts) versus temperature. The first glow curve is for a natural sample (*N*), and the second curve is for a natural sample that has been given a laboratory dose of radiation (*N*+dose). Note that the *N*+dose curve shows TL measured below approximately 200 °C, which has resulted from electrons in traps that are thermally unstable over geological time, with the electrons having been put there as a result of laboratory irradiation (see also [Figure 2](#)). Based on Figure 1.2 of [Aitken \(1985\)](#).

dose–response curve, as is done with the additive dose method discussed previously. In the case of the partial bleach method, however, some of the aliquots are given a short exposure to laboratory light (or natural sunlight) following laboratory dosing. Both data sets are fitted with suitable curves, and these are extrapolated to the point where they intersect above the dose axis. As with the additive dose and total bleach methods, dose axis-intercept values are determined at successively increasing temperatures until a plateau is achieved, and the equivalent dose is determined from it ([Figure 3\(b\)](#)). A modification of the partial bleach method is the selective bleach method ([Prescott and Mojarrabi, 1993](#)). This method is based on the fact that traps emptied at ~325 °C are significantly more sensitive to sunlight than others measured between 300 and 500 °C ([Franklin and Hornyak, 1990](#); [Prescott and Fox, 1990](#)). In practice, aliquots used for the partial bleach data set are selectively bleached with light of a wavelength of ~425 nm (green) or longer, and then the 380 nm TL associated with the 325 °C trap is measured for all aliquots.

If extrapolation of the dose–response curve(s) to the dose axis is large, the regeneration technique should be used. In its simplest form, it involves interpolation of the TL intensity of a natural sample aliquot onto its additive dose curve, and the equivalent dose is determined from that point's position on the curve above the dose axis. In its most complete form, the regeneration method involves constructing a regenerative dose–response data set in addition to the additive dose data set. The regenerative data set is produced by bleaching some of the sample aliquots for an extended time so as to empty all the light-sensitive traps and then giving them various laboratory radiation doses. The data points (laboratory dose values) that define the regenerative dose–response are chosen so as to largely overlap those that define the additive dose–response. The additive dose data set is then shifted along the dose axis to where it coincides with the regenerative dose data set, with the magnitude of the shift being equal to the equivalent dose after a correction for incomplete laboratory bleaching. A requirement of the technique is that the dose–responses of

Figure 2 Example of the additive dose method used for finding the equivalent dose of a sediment sample that has been heated so that all the relevant electron traps have been emptied. The example is for fluvial silt that was heated by fire approximately 15 000 years ago. Aliquots of the sample are prepared; some are left as it is (the naturals, N), whereas others are given various doses of laboratory radiation ($N + \text{dose}$ data points), in this case from a ^{60}Co gamma (γ) source. Typically, several aliquots are used at each dose point. The TL from the sample aliquots is measured, resulting in glow curves that have peaks representing different electron traps; as the temperature increases, progressively deeper, or more thermally stable, traps are being emptied. Inset (a) shows the dose–response determined from the TL that was measured between 355 and 360 °C, and the dose axis intercept is found as shown. Inset (b) shows dose axis intercepts plotted as a function of glow curve temperature and the formation of a TL plateau at approximately 350 °C that corresponds to an equivalent dose of approximately 80 Gy. Modified from Figure 1 of Lian OB and Huntley DJ (2001) *Luminescence dating*. In: Last, WM and Smol JP (eds.) *Tracking Environmental Change Using Lake Sediments, vol. 1: Basin Analysis, Coring, and Chronological Techniques*, pp. 261–282. Dordrecht, The Netherlands: Kluwer.

both the additive dose and regenerative data sets are identical. This regeneration method is often called the Australian slide method (Prescott et al., 1993) due to its extensive use on the 1 million year-old stranded dune sequence in South Australia.

All of the protocols discussed previously involve constructing a sample's dose–response using either laboratory gamma or beta radiation. In the environment, a sample is also irradiated by alpha particles, which are less efficient in producing free electrons than are gamma or beta radiation. For sand-sized grains, the alpha-affected surfaces are removed by etching with acid, but this is impractical for silt-sized grains. Therefore, if silt-sized grains are to be dated, their alpha efficiency must be determined and included in the dose-rate calculation. This is done by constructing a separate alpha dose–response curve and comparing the equivalent dose found from it with that found using either gamma or beta radiation; see Aitken (1985) for a thorough discussion.

The wavelength (i.e., energy) of the TL emitted from a sample depends on the minerals present and the nature of the electron traps (i.e., the types of impurities and defects present) sampled during heating. The wavelength range that can be measured is largely dependent on the sensitivity of the detector (photomultiplier tube; Figure 1); most of these can only detect wavelengths below approximately 600 nm. This, together with the fact that light resulting from incandescence emitted at high temperatures must be avoided, means that blue or shorter

wavelengths typically are used for dating. In practice, optical filters are used to separate out the desired part of the spectrum (Figure 1). Blue pass filters are commonly used for quartz, and both blue and ultraviolet pass filters are used for feldspar dating. The choice of wavelength does have a bearing on the equivalent dose, but the relationship between the two is not clear (Berger et al., 1994). However, the ultraviolet TL from feldspar does bleach more quickly with sunlight exposure time than does the blue emission (see Aitken, 1985, Figure 8.8).

Determining the Dose Rate

The dose absorbed by the sediment grains of interest comes from alpha, beta, and gamma radiation emitted during the decay of ^{235}U , ^{238}U , ^{232}Th , ^{40}K , and ^{87}Rb and their daughter products, within both the mineral grains and their surroundings. Another component of the absorbed dose comes from cosmic rays, which consist of highly energetic particles originating from unknown sources in outer space. The intensity of cosmic rays diminishes with depth beneath the ground surface, and the rate at which it diminishes is related to the density of the material through which they are passing. The intensity of cosmic rays at the surface also varies with latitude and elevation and with fluctuations in Earth's magnetic field (Prescott and Hutton, 1994). The radiation dose absorbed by the minerals of interest depends not only on the concentration of the

Figure 3 Examples of the total bleach and partial bleach methods for determining equivalent dose. (a) The total bleach method. Several sample aliquots are prepared; some are left as it is (naturals, N), whereas others are given various laboratory doses, in this case for a ^{60}Co gamma (γ) source, ($N + \gamma$ set). These data are fitted with a curve, which is extrapolated (dashed line) to where it intercepts the TL intensity measured from a natural aliquot that has been given a long exposure to light ($N + \text{bleach}$) so that only electrons in the most light-insensitive traps remain, which give rise to I_0 (see text). The inset at the bottom shows the TL glow curves for this sample. The inset at the top shows intercept values plotted as a function of progressively increasing temperatures; an intercept (TL) plateau is formed between ~ 300 and 330°C , and from it the equivalent dose (D_e) is estimated to be ~ 480 Gy. The data are for K-feldspar medium sand, and they gave a TL age between 240 and 290 ka. (b) The partial bleach method. The data are essentially the same as for the total bleach method shown in (a) except another (lower) curve is constructed from data measured from a set of aliquots that have been given various laboratory doses, followed by a restrictive bleach so that only the most light-sensitive traps are emptied ($N + \gamma + \text{bleach}$ set). Both curves are extrapolated (dashed lines) to where they intersect above the dose axis. As in (a), intercept values are determined as a function of temperature (inset graph), and the dose at which they become constant is taken to be the D_e , which is estimated to be ~ 225 Gy in this case. The TL, presumably from K-feldspar, was measured from fine silt polymineral grains extracted from an ~ 110 ka organic-rich (peaty) sediment. Optical filters in front of the photomultiplier tube included a Schott KG-1 (to absorb unwanted incandescence) and Schott BG-39 and Kopp 5-58 blue pass filters. The sample aliquots were preheated at 130°C for 5 days prior to TL measurement to minimize the effects of anomalous fading. From Lian OB and Roberts RG (2006) Dating the Quaternary: Progress in luminescence dating of sediments. *Quaternary Science Reviews* 25, Figure 2: the graphs in (a) are based on Figure 3 of Balescu and Lamothe (1993), and the graphs in (b) are modified from Figure 4(d) of Lian et al. (1995).

radioisotopes mentioned previously, and the intensity of cosmic rays, but also on the quantity of water and organic matter in the sediment matrix because these attenuate or absorb radiation differently from the mineral matter. All of these quantities have to be determined and included in the dose-rate calculations. General formulas used to calculate dose rate from concentrations of ambient U, Th, and K can be found in Aitken (1985, 1998), whereas the latest dose-rate conversion factors for these radioisotopes are those of Adamiec and Aitken (1998). Methods for estimating the contribution to the dose rate of beta particles emitted during the decay of ^{40}K and ^{87}Rb within K-feldspar grains are discussed by Huntley and Baril (1997) and Huntley and Hancock (2001), respectively, and the beta attenuation factors can be found in Mejdahl (1979). Those for ^{87}Rb have been updated by Readhead (2002a,b). Formulas modified to account for the occurrence of organic matter in the sediment matrix were developed by Divigalpitiya (1982) and can be found in Lian et al. (1995). The formula used to estimate the dose rate due to cosmic rays at a sample site is found in Prescott and Hutton (1994).

Radioisotope concentrations are determined by taking a representative subsample of the bulk (unprepared) fraction used for dating and employing a variety of laboratory analyses that give the concentration of the parent isotopes or of the various daughter products in the decay chains, from which the concentration of the parents can be determined. The assumption is that the isotopes of interest have remained in secular equilibrium throughout the lifetime of the sedimentary deposit that was sampled. In most instances this is the case, but there are situations in which the parent isotopes and/or the daughters have been removed from the sample site or have been introduced to it. For example, ^{222}Rn (a daughter product of ^{238}U) can leave by gaseous diffusion, and U, which is soluble in groundwater, can be leached away from a site or

be taken up by organic matter at the site. It is often difficult or impossible to determine if radioactive disequilibrium has occurred at a sample site in the past, but one can easily determine if it exists at the time of sample collection. This is done by measuring the activities of various daughter products in the decay chains. Some forms of disequilibrium are time dependent and, if significant, should be taken into account when the dose rate is calculated. Papers relevant to TL dating that discuss and assess radioactive disequilibrium for various sedimentary environments, and suggest ways to deal with it, are those of Prescott and Hutton (1995), Olley et al. (1996, 1997, 2004), Stokes et al. (2003), and Berger (2006).

Another variable that can complicate dosimetry at a sample site is variability in the sediment matrix. Beds or lenses of significantly different material (e.g., zones where heavy minerals are concentrated) that occur within 50 cm of the sample location can contribute significantly to the gamma dose delivered to the sample site. In such cases, the dose rate calculated from the material in the sample alone will be inappropriate, and *in situ* measurements are required. This can be done in the field using a portable gamma-ray spectrometer (Figure 4). Other options, albeit more laborious, are to calculate the dose rate from samples collected from the various strata or lenses surrounding the sample site and use these data to model the dose absorbed by the sediments to be dated (see Aitken, 1985, Appendix H) or to use *in situ* TL dosimeter capsules (Aitken, 1985, 1998).

Barring the existence of significant disequilibrium in the U decay chain, the largest uncertainty in the dose-rate calculation is commonly that associated with pore water content in the sediment matrix. This is especially so in cases in which water content has fluctuated significantly over time, such as would be expected in environments in which standing or flowing water once existed, such as former lake bottoms, bogs, glacier or ice

Figure 4 Example of a portable gamma-ray spectrometer (Exploranium model GR256). The instrument consists of a long cylindrical probe (shown inserted at the sample site) in which a sodium iodide crystal and a photomultiplier tube together serve as the detector; the probe is connected to electronics that record the gamma-ray spectra. Also shown at the lower left-hand side of the case is a handheld computer that is used to control the spectrometer and to upload data. Portable gamma-ray spectrometers are able to detect gamma rays from ^{40}K and from late daughters in the U and Th decay chains from which the concentrations of the parent isotopes can be calculated, assuming secular equilibrium.

sheet beds, and stream beds. In such cases, usually the best that can be done is to use an average water content value with an error term that will cover both extremes – dry and water saturated – at 2 standard deviations. In such extreme cases, the uncertainty associated with the past water content may contribute $\pm 10\%$ to the uncertainty in the calculated TL age. If one wishes to date sediments extracted from organic-rich environments, such as paleosols or fossil peat bogs, then the organic content of the bulk sample needs to be measured as well as water content, and as mentioned previously, the degree of disequilibrium must be assessed because organic matter absorbs uranium from groundwater (e.g., [Lian et al., 1995](#)).

Sample Collection and Preparation

Although sample collection for TL dating is relatively simple, it should be done by someone from the dating laboratory, together with a geoscientist familiar with the environmental history of the site and the region, so that the best sampling strategy can be established.

A sediment sample is usually collected by inserting a metal or opaque hard plastic open-ended cylindrical container into the cleaned section face (see [Wagner, 1998, Figure 94](#)). The container is then carefully excavated and the ends are promptly sealed to preserve the water content. Another technique suitable for cohesive deposits involves carving out a sediment block (see [Lian and Huntley, 2001, Figure 8\(b\)](#)) and wrapping it in several layers of aluminum foil for protection; a few millimeters of sediment is removed from the light-exposed surfaces in the laboratory before the block is sampled for dating. Sample collection is discussed in more detail by [Lian and Huntley \(2001\)](#) and [Wallinga \(2002\)](#).

The amount of sediment needed for TL dating depends on the desired grain size, the available amount of quartz and/or feldspar, and which dosimetry techniques will be employed, so it is useful to have some prior information about the grain size content of the sample. Typically, ~ 1 kg of material is sufficient, but there have been instances in which less than 1 g has been enough and other cases in which more than several kilograms have been needed. Obviously, for very large samples one has to be concerned about sampling across regions with very different ages.

Samples are prepared in a special laboratory under subdued orange or red light. Preparation usually involves two steps: (1) chemical treatments to remove carbonates, organic matter, and feldspars (if only quartz is to be dated) and to disperse (deflocculate) clay, and in some cases treatments are administered to remove TL-blocking oxidation coatings from the mineral grains; and (2) separation of the sample into the desired mineral types and grain sizes using sieves, heavy liquids, and settling in water if the fine silt fraction is required. The most common grain sizes used for TL dating are in the fine silt range – 2–8 or 4–11 μm diameter – or a range in the fine to medium sand fraction, such as 90–125 or 250–350 μm diameter. These size fractions are chosen because they are common in most depositional environments and because the microdosimetry has been well defined for them, but other grain sizes can be used as well. The laboratory techniques used to prepare a sample for dating are discussed in detail by [Wintle \(1997\)](#);

see also [Lian et al. \(1995\)](#) or [Lian and Shane \(2000\)](#) for samples that contain a significant organic component.

Environments Suitable for TL Dating

Any sedimentary deposit that contains an adequate amount of quartz and/or potassium feldspar grains in the desired size fraction, which has been exposed to sufficient sunlight or heat prior to final burial, has the potential for yielding an accurate TL age. Therefore, the most suitable environments are those in which the sediment has been transported over considerable distances in the atmosphere and/or have been reworked by other processes at the ground surface for an extensive amount of time before finally being buried. Much of TL dating of sediments has therefore been done on eolian deposits such as loess and beach dune sediment. Reviews of the application of TL dating to eolian sediments (especially loess) can be found in [Readhead \(1988\)](#), [Berger \(1988a,b, 1992a, 1994, 1995\)](#), [Wintle \(1990, 1993\)](#), [Zöller and Wagner \(1990\)](#), [Prescott and Robertson \(1997\)](#), and [Wagner \(1998\)](#). One of the most extensive and detailed TL dating studies was that done on the 0–800 ka stranded beach dune system in South Australia ([Huntley and Prescott, 2001](#); [Huntley et al., 1993, 1994](#)). These workers were able to demonstrate that their methods could produce TL ages from quartz sand between zero and at least 500 ka that were consistent with high sea-level stands that had been associated with marine oxygen isotope stages of known age ([Figure 5](#)); older ages were also obtained for dunes occurring further inland, but the accuracy of these ages is questionable ([Huntley and Prescott, 2001](#)). Other notable examples include those of [Berger et al. \(Berger, 1992a; Berger et al., 1994\)](#), who TL dated the fine silt feldspar fraction of loess of known age from Alaska and New Zealand and concluded that accurate ages up to 800 ka could be attained ([Figure 6](#)), although [Prescott and Robertson \(1997\)](#) questioned whether there is enough evidence to make this claim.

Sediments from many other environments have received attention as well, but with mixed results. These include those deposited in fluvial, colluvial, lacustrine, marine, peat bog, and pedogenic systems (see reviews by [Berger, 1995](#); [Prescott and Robertson, 1997](#); [Wagner, 1998](#); [Walker, 2005](#)). Heated sediments such as those that can be found directly underlying lava flows ([Forman et al., 1994](#); [Robertson et al., 1996](#)) can be dated by TL, and often tephra can be as well ([Berger, 1985, 1992b](#); [Berger and Basacca, 1995](#)).

Factors that Can Lead to an Inaccurate TL Age

The most significant factor that can lead to an inaccurate TL age is that the mineral grains comprising a sample collected from a sedimentary deposit have not all been exposed to sufficient heat or sunlight prior to burial. In such cases, the calculated TL age will lie somewhere between the true age of the deposit and the apparent age of its parent material(s). An inaccurate TL age can also result if an inappropriate protocol is chosen for determination of the equivalent dose; if an inappropriate curve is fitted to the dose–response data ([Wagner, 1998, Figure 81](#));

Figure 5 Cross-section through the stranded beach dunes at Robe, South Australia. The black dots show where samples were collected for dating. The TL ages for these are shown to correlate with peaks in the marine oxygen isotope curve, which are associated with sea-level-high stands. In many cases, the TL ages calculated were also consistent with other chronological information. In each case, the mineral dated was quartz, and a regeneration technique (Australian slide method) was used to find the equivalent dose. Two Kopp 7–59 optical filters were used to select the blue TL emission band. For many of the samples, a preheat procedure (166 °C for 33 h) was employed to isolate the rapidly bleached 325 °C TL peak from adjacent peaks. Reproduced from Huntley DJ and Prescott JR (2001) Improved methodology and new thermoluminescence ages for the dune sequence in southeast South Australia. *Quaternary Science Reviews* 20: 687–699, Figure 1. Reproduced with permission. See also [Huntley et al. \(1993, 1994\)](#).

if TL from part of the glow curve that represents electron traps that are difficult to bleach is used to construct the dose-response curve ([Prescott and Mojarabi, 1993](#); [Spooners, 1998](#)); if supralinearity in the low-dose part of the dose-response curve exists and it is not taken into account ([Aitken, 1985](#); [Wagner, 1998](#)); if so-called spurious (i.e., nonradiation-induced) TL is inadvertently measured ([Aitken, 1985](#)); or if there is, or has been, significant radioactive disequilibrium at the sample site. More complex phenomena that can cause problems are the presence of second-order kinetics, for which the position of the TL peaks is dependent on the radiation dose absorbed by a sample ([Aitken, 1985](#); [McKeever and Chen, 1997](#)), and, if feldspars are dated, anomalous fading ([Aitken, 1985](#); [Visocekas, 1985](#); [Wintle, 1973](#)), which refers to the loss of electrons at ambient temperatures, probably by quantum-mechanical tunneling, from traps that are expected to be thermally stable over geological time. The presence of all these malign effects, with perhaps the exception of anomalous fading, can be detected by the absence of a TL plateau. Some workers maintain that the effects of anomalous fading can be avoided by first heating (preheating) the sample at a low temperature for an extended period of time (e.g., 100 °C for 1 week; [Wintle, 1997](#)) before the TL is measured, by dating the fine silt fraction ([Berger, 1995](#)), or by measuring an appropriate TL emission wavelength. Other workers, however, maintain that anomalous fading cannot be circumvented, and if it is

significant in a sample, then the sample cannot be dated unless the fading can be corrected for.

Recent Advances in TL Dating

TL dating of unheated sediments has been largely replaced by optical dating, although TL dating still has an important role in dating heated materials. The main reasons that optical dating is now preferred over TL dating are that (1) the traps sampled for optical dating are much more sensitive to light than those measured for TL, and (2) optical dating protocols allow for the measurement of very small samples, often as small as a single grain of sand. Despite the establishment of optical dating, in some cases it cannot be applied to unheated sediments. These include instances in which anomalous fading cannot be avoided or for which it cannot be corrected (if feldspars are selected) or cases in which the mineral grains of interest emit optically stimulated luminescence that is too dim to be used effectively for dating (as is the case for some quartz samples). These problems have prompted some workers to revisit TL dating. One of most important advances has been the development of a dual-aliquot protocol for TL dating using the light-sensitive isothermally stimulated red TL emission that is prevalent in many quartz samples derived from volcanic rock ([Westaway and Roberts, 2006](#)). This technique allows for the

Figure 6 Graph showing TL age versus expected age (~18–800 ka) for various fine silt loess polymineral samples from Alaska and New Zealand; the measured TL was presumably from feldspar. In each case, sample aliquots were preheated before measurement (various temperatures and durations were used; see Berger et al., 1992, for details). Error bars are two standard deviations. Ages for most of the samples were calculated from equivalent dose values found using both the total bleach and partial bleach methods and either a UG11 (ultraviolet pass) or BG28 (blue pass) optical filter between the sample and the detector (photomultiplier tube). Berger et al. concluded that for all except two of their samples, the choice of output filter had no significant bearing on calculated TL age. They also concluded that for their samples, the partial bleach method could produce accurate TL ages up to approximately 350 ka, and that the total bleach method could yield accurate ages for samples in the range 100–800 ka. See also Berger et al. (1994) for a more detailed analysis and discussion of these samples; a critical discussion of this work can be found in Prescott and Robertson (1997). Modified from Berger GW, Pillans BJ, and Palmer AS (1992) Dating loess up to 800 ka by thermoluminescence. *Geology* 20: 403–406; Figure 3.

measurement of very small samples and helps eliminate some of the uncertainty inherent in the standard multiple-aliquot protocols, namely that associated with the assumption that the dose–response of every aliquot in a set is identical. This dual-aliquot method also allows information to be gained on equivalent dose distributions in samples consisting of grains with different age populations.

Another advance in TL dating includes the use of the red TL emitted from most feldspars, which has been shown not to suffer from anomalous fading, at least for the samples studied (Zink and Visocekas, 1997; see also the review by Fattahi and Stokes, 2003). One drawback of the aforementioned techniques is that a special photomultiplier tube is needed to detect the red TL. Finally, workers have also sought to employ the isothermal blue TL signal to extend the age range of quartz (Jain et al., 2005). It should be noted, however, that these new techniques are in developmental stages and therefore should not be used alone for routine dating until they have been thoroughly tested.

Optical Dating

O B Lian, University of the Fraser Valley, Abbotsford, BC, Canada

Introduction

Optical dating, sometimes referred to as optically stimulated luminescence (OSL) dating, is based on the fact that natural minerals can absorb and store ionizing energy. If a mineral is exposed to sufficient light (e.g., sunlight), or heated to a high temperature ($\sim 500^\circ\text{C}$), some or all of this stored energy will be lost.

In the environment, the energy absorbed by a mineral comes from radiation emitted from radioisotopes within the mineral grain, from its immediate surroundings, and from cosmic rays. The rate at which a dose of radiation energy is absorbed by a mineral (the dose rate) is therefore proportional to the concentrations of radioisotopes, and to the intensity of cosmic rays at the sample site. Simply put, for a given mineral sample, what is needed to determine an optical age is (1) the laboratory dose of radiation that produces the same intensity of OSL as did the environmental radiation dose (called the equivalent dose) and (2) a measure of the environmental dose rate. An optical age is simply the equivalent dose divided by the dose rate. Optical dating therefore gives the time elapsed since mineral grains were last exposed to sufficient sunlight or heat.

Optical dating developed from thermoluminescence (TL) dating in the mid-1980s (Huntley et al., 1985). Its main advantage over TL dating is that only the most light-sensitive OSL signal is sampled, which allows for much younger samples to be dated. Moreover, the optical dating experiments needed to produce an equivalent dose are generally simpler than those required for TL dating, which usually results in better precision. Optical dating has therefore all but replaced TL dating for unheated sediments. Optical and TL dating are part of a family of chronological techniques collectively referred to as trapped charge dating. Related methods include electron spin resonance (ESR) dating and radioluminescence dating (e.g., Krbetschek et al., 2000); discussion of ESR dating can be found elsewhere in this encyclopedia.

The Mechanism Responsible for OSL

Luminescence refers to the light emitted by matter when it is subjected to external stimulation. When this external stimulation is photons of visible light, the luminescence emitted is referred to as OSL; it is called infrared-stimulated luminescence (IRSL) if the stimulation is from far-infrared photons. In the discussion below, for simplicity, both phenomena are referred to as OSL unless additional detail is needed. The physical models used to explain the OSL phenomena are complex and not fully understood; general, and varied, accounts, most of which are relevant to dating, can be found in Aitken (1998), Wintle (1997), McKeever and Chen (1997), Bailey (2001), Bøtter-Jensen et al. (2003), Preusser et al. (2009), and McKeever and Yuhikara (2011).

Briefly, crystals, such as those comprising natural minerals, are not perfect, and contain impurities and structural defects, some of which are attractive to electrons that have been freed from their normal sites in the valence bands of atoms; these sites are referred to as electron traps. Free electrons are produced when atoms absorb ionizing radiation that occurs in the natural environment. Free electrons may subsequently be held in traps for a time that depends on the strength, or thermal lifetime, of the particular trap. For dating, only those traps that can hold electrons at environmental temperatures over geological time (thermally stable or 'deep' traps) are of interest. Further detail can be found in reference to TL dating.

Some of these traps can be emptied (bleached) by exposure to light. Of the light-sensitive traps responsible for OSL, some can easily be emptied by a brief exposure (e.g., a few seconds) to direct sunlight, but there are others for which a much longer sunlight exposure is needed. In any one mineral grain, therefore, there are many different types of electron trap that can contribute to OSL, and these have different sensitivities to light. In the laboratory, OSL is produced by exposing a sample to light (photons) of a specific wavelength, or wavelength range, thus freeing electrons from light-sensitive traps. Some of these freed electrons quickly recombine at other sites where excess energy is given off as luminescence (the OSL). The output is what is commonly referred to as a shine-down curve, which consists of OSL intensity plotted as a function of light stimulation (sometimes referred to as excitation) time (Figure 1(a)). For a given mineral grain, the intensity of the measured OSL is related to the number of filled electron traps. If irradiation continues, traps will fill until an additional dose of radiation will not result in more OSL being measured; this condition is referred to as saturation and it is one of the factors that sets the upper age limit for the method. The shape of the shine-down curve reflects the different electron trap populations present in the mineral, the initial OSL coming from the most light-sensitive traps, and subsequent OSL arising from traps that are not as light sensitive. A single shine-down curve can, therefore, be composed of the sum of several exponential decay curves, each associated with a different electron trap population with a specific sensitivity to light. Smith and Rhodes (1994) concluded that the shine-down curve for quartz consists of three components which they referred to as fast, medium, and slow, depending on how easily they could be bleached, while others have identified at least seven components for this mineral (Jain et al., 2003). It is not known exactly how many components exist in any one mineral grain, but they could theoretically form a continuum. It is becoming generally accepted that for quartz the OSL measured over the initial part of the shine-down curve, that recorded from when the stimulating beam is switched on until $\sim 5\%$ of the initial OSL signal remains (the fast component), is thermally stable and can be used to determine accurate age estimates, while the OSL recorded over subsequent time intervals (from the

Figure 1 Instrumentation used to stimulate and record optically stimulated luminescence (OSL). (a) Schematic illustration of a single-sample apparatus. Light (photons) of wavelength λ_1 are emitted from high-power blue or infrared light-emitting diodes (LEDs) and are focused onto a sample aliquot, which is inserted manually into the apparatus by means of a drawer that extends perpendicular to the drawing. Photons of a shorter wavelength, λ_2 (the OSL), are emitted in response and are collected by an ellipsoidal mirror, which, in turn, directs them to the photomultiplier tube (PMT; the detector). A discussion of the principles behind the photomultiplier tube can be found elsewhere in this encyclopedia. The optical filter(s) immediately above the mirror are used to absorb photons from the LEDs that are of a shorter wavelength (higher energy) than λ_1 , while the optical filters immediately above the PMT are used to block scattered photons from the stimulation source (LEDs, in this case) and other unwanted photons (e.g., see Lian and Huntley, 2001). The output from the PMT is fed through electronics (not shown), and the result is a shine-down curve, such as the one depicted in the inset figure. The shine-down curve shows the OSL recorded as a function of stimulation time, and reflects the progressive depletion of trapped electrons. The greater the number of filled electron traps at the time of sample collection, the greater the intensity of measured OSL when the LEDs are switched on. Note that the shine-down curve does not show a simple exponential decay, but the sum of various decay curves, each representing a population of electron traps with a particular sensitivity to light. Based on Figure 3 of Lian OB and Huntley DJ (2001) *Luminescence dating*. In: Last WM and Smol JP (eds.) *Tracking Environmental Change Using Lake Sediments, Vol. 1: Basin Analysis, Coring, and Chronological Techniques*, pp. 261–282. Dordrecht: Kluwer. (b) Schematic representation of one of the automated luminescence readers that is available commercially: the Risø TL/OSL reader. In its basic form, the machine consists of a sample carousel which is used to move aliquots (up to 48 in a run) either to a position where they can be irradiated (by a shielded $^{90}\text{Sr}/^{90}\text{Y}$ beta source in this case), or to a position under a PMT where luminescence (OSL or IRSL) can be measured. In the latter position, the temperature of the aliquot can be raised, as is required for TL or single-aliquot OSL measurements. Optional attachments (not shown) include a system for measuring radioluminescence, an X-ray generator (as an alternative to the beta-source irradiator), and an apparatus for irradiating and measuring single grains. See Bøtter-Jensen et al. (2003) for details. Drawing reproduced from Bøtter-Jensen L, McKeever SWS, and Wintle AG (2003) *Optically Stimulated Luminescence Dosimetry*. Amsterdam: Elsevier.

medium and slow components, etc.) should be avoided (Bai-ley, 2010).

Generating and Measuring OSL for Optical Dating

The first instruments designed to measure OSL (e.g., as in Figure 1 of Huntley et al., 1985) were developed from those used to measure TL. Instruments used for optical dating are much simpler than those used for TL dating as they do not usually require that the sample chamber be evacuated, and a sample can usually be measured in air, whereas for TL dating an inert gas atmosphere is needed. These simplified measurement requirements usually lead to better precision. The first optical dating instruments could only hold one aliquot of sediment at a time, aliquots had to be changed manually, they required a separate irradiator facility, and gas lasers, such as the argon ion laser used by Huntley et al. (1985), were used for the stimulating light source. Expensive lasers were soon replaced by filtered quartz-halogen or xenon-arc lamps, and then eventually by more affordable high-power light-emitting diode (LED) arrays. The instruments also became automated with the irradiator unit mounted on board, and they could measure many aliquots in a run while keeping them at an elevated temperature, as is usually required for single-aliquot techniques (Figure 1).

As with the earlier TL dating apparatuses, current optical dating instruments require a photomultiplier tube (PMT) as a detector, and this typically is mounted above the sample (aliquot) position with space for optical filters between them (Figure 1(a) and 1(b)). Recent advances in commercial instrumentation include attachments to measure pulsed OSL, radioluminescence, focused semiconductor lasers as stimulating sources for single-grain dating, and X-ray generators as an alternative to shielded beta-source irradiators. Reviews and discussion of optical dating instrumentation can be found in Aitken (1998), Bortolot and Bluszcz (2003), Bøtter-Jensen et al. (2003), and Thomsen et al. (2008a).

Optical Dating

As mentioned earlier, what is required to calculate an optical age is to measure the environmental dose rate, and to make an estimate of the equivalent dose. These are discussed in turn below.

Determining the Environmental Dose Rate

The dose of radiation absorbed by the sediment grains of interest comes from alpha and beta particles, and from gamma rays emitted during the decay of ^{235}U , ^{238}U , ^{232}Th , ^{40}K , and ^{87}Rb , and their daughter products, both within the mineral grains and in their surroundings; another component of the absorbed dose comes from cosmic rays, which consist of highly energetic particles originating from unknown sources in the universe. All of these quantities have to be determined and included in the dose-rate calculations, as well as the pore-water content, and, in some cases, the organic content of the sediment matrix, as these attenuate or absorb radiation differently

than does mineral matter. The term dose refers to the amount of radiation energy absorbed per kilogram of matter. The SI unit for dose is the gray (Gy), where $1\text{ Gy} = 1\text{ J kg}^{-1}$. Dose rate commonly is denoted by $\dot{D}_T$ (where the subscript 'T' indicates the total dose rate, that due to alpha, beta, gamma, and cosmic-ray radiation) and it has units of Gy ka^{-1} or mGy a^{-1} .

General formulae used to calculate dose rate from the concentrations of radioisotopes in the environment, and from the intensity of cosmic rays, can be found in Aitken (1985, 1998), and in Prescott and Hutton (1994), respectively. Dose-rate formulas that take into account organic content can be found in Lian et al. (1995). Factors that can reduce the accuracy and precision of a calculated dose-rate value are (1) radioactive disequilibrium in the U and/or Th decay chains, (2) mineral inhomogeneity in the sediment matrix, (3) uncertainty about a sample's depth beneath the ground surface over the lifetime of the deposit (which adds uncertainty to the cosmic-ray dose rate), (4) uncertainty about the water content history at the sample site, and (5) analytical uncertainties associated with the procedure and instrumentation used to measure radioisotope concentrations. These topics are discussed in more detail elsewhere in this encyclopedia.

Estimating the Equivalent Dose

Equivalent dose, measured in grays (Gy, defined above), is found by recording how a sample's OSL intensity responds to increasing doses of laboratory radiation; this is referred to as a sample's dose response. The term equivalent dose is used because the laboratory radiation used to construct a sample's dose response consists only of gamma rays or beta particles (or sometimes X-rays), whereas in the natural environment the radiation absorbed by a sample comes from alpha and beta particles, gamma rays, and cosmic rays. Equivalent dose is represented by the notation ED , D_{eq} , or D_e , and is sometimes referred to loosely (and incorrectly) as paleodose.

One of the main differences between TL dating and optical dating is that for optical dating there is no way of selecting during measurement only those electron traps that are thermally stable over geological time. To overcome this problem, the sample aliquots are heated (preheated) prior to measurement. The objective of the preheat is to empty all of the thermally unstable electron traps, while leaving most of the thermally stable traps full; the former traps are filled during laboratory irradiation. The temperature and duration used for the preheat is, to a degree, specific to the sample, so in practice the severity of the preheat is increased until the equivalent dose determined becomes constant. Preheating a sample does, however, have some malign side-effects that have to be assessed, and, if severe, taken into account. One of these unwanted side-effects is that preheating changes the OSL sensitivity of the mineral grains, and another is that it causes electrons to be transferred from thermally stable light-insensitive traps to the thermally stable light-sensitive traps relevant to dating. The degree of this thermal transfer depends on the amount of electrons in thermally stable light-insensitive traps, and this, in turn, is related to the amount of light exposure that the sample received in the environment prior to burial, and on the magnitude of the laboratory radiation dose(s) given to the sample.

Several procedures are currently available that can be used to estimate equivalent dose. These protocols can be divided into those which require many aliquots of a sample, and those that need only one aliquot. Of the latter, a single aliquot can comprise hundreds or thousands of individual sediment grains, or it can consist merely of one grain of sand. Methods used to find equivalent dose are summarized below, while detailed discussions, with various emphases, can be found in, for example, Aitken (1998), Murray and Wintle (2000, 2003), Duller (2004), Wintle and Murray (2006), Lian and Roberts (2006), Jacobs and Roberts (2007), Duller (2008), and Wintle (2008).

Multiple-Aliquot Techniques

The multiple-aliquot procedures were the first protocols designed for optical dating and they evolved from those used for TL dating. They include the additive-dose method, the additive-dose with late-light subtraction technique, the additive-dose with thermal-transfer correction (ADTT) method, and the regeneration methods. All these protocols require that ~20–50 aliquots of a sample to be prepared. These aliquots are then given various laboratory radiation doses, in some cases several are exposed to light (i.e., they are bleached for a specific duration using a filtered laboratory light source, or natural sunlight) before or after irradiation, depending on the protocol, and then their OSL is measured using apparatuses like those described above. The OSL data are used together to deduce the sample's dose response, and from that an equivalent dose is estimated.

The additive-dose method is the simplest protocol, and it was the one used in the initial trials by Huntley et al. (1985). This method requires that several aliquots of a sample are left as is (the so-called naturals, commonly denoted by N), while several others are each given progressively increasing doses of laboratory radiation ($N + \text{dose}$). All the aliquots are then preheated and measured, usually after a delay. The luminescence intensity is then plotted as a function of laboratory radiation dose. A curve is fitted to these data, and extrapolated to where it intercepts the dose axis, the intercept point being the equivalent dose (e.g., as is shown in Figure 1A of Wintle, 2008). If a sample consists of grains that have all received sufficient sunlight exposure prior to burial, and if the shine-down curve consists of only one component, or of components that all represent light-sensitive thermally stable traps (which is commonly not the case for quartz – see, e.g., Bailey, 2000, but which might be the case for feldspar), then it should not matter which part of the shine-down curve is used to construct the dose response. That is, the intercept values will be constant with stimulation time; this is sometimes referred to as a shine plateau. On the other hand, intercept values will increase with stimulation time if the sample consists of grains that have not received sufficient sunlight prior to burial. Unfortunately, this indicative rise in intercept values with stimulation time will not occur if the sample consists of a population of grains that have been exposed to sufficient sunlight, mixed with one or more populations of grains that have not. A modification of the additive-dose technique is the late-light subtraction method (Aitken, 1998): aliquots are irradiated, preheated, and

measured in the manner described above, except that the OSL recorded during an interval of time at the end of the shine-down curve (the so-called late-light) is subtracted from the initial OSL used to construct the dose response. The idea is that this late-light consists mainly of scattered photons from the stimulation beam, background photon counts from the detector (PMT), and OSL arising from electrons remaining in hard to bleach traps. The time interval selected for the late-light clearly depends on the power of the stimulating beam at the sample.

The main limitation of the additive-dose and late-light subtraction methods is that if thermal transfer resulting from the preheat procedure is significant, a calculated optical age will be too old. This problem is, however, taken into account with the ADTT technique (Huntley et al., 1993). For the ADTT technique, a subset of the irradiated aliquots that are to be used to construct the dose–response curve are given a short exposure to natural sunlight or laboratory light ($N + \text{dose} + \text{bleach}$) so as to empty all of the electrons in light-sensitive traps, but leaving full the light-insensitive traps that are the source of the thermal transfer. The two sets of aliquots are then preheated together and measured. Curves are fitted to both data sets, and these are extrapolated to where they intersect above the dose axis, and the dose there is taken as the intercept value. The ADTT method not only corrects for thermal transfer, but accounts for background photon counts from the detector, scattered photons from the stimulation source, and Raman-scattered photons. As with the additive-dose method, dose-intercept values should be constant with stimulation time if only thermally stable components of the shine-down curve are sampled and all the light-sensitive traps in all the sample grains measured had been emptied in the environment before burial. An example of the ADTT method is shown in Figure 2. If extrapolation of the dose–response curve(s) to the dose axis is large, as is the case for most old samples, then the regeneration method should be used. In its most basic form, the regeneration method involves giving several sample aliquots an extended exposure to light so as to empty as many light-sensitive traps as possible, and then using these aliquots to construct a regenerative dose–response curve by giving them various radiation doses ($N + \text{bleach} + \text{dose}$). The OSL intensity from a natural aliquot is then interpolated onto the regenerative dose–response curve, the equivalent dose being the corresponding value of this point on the dose axis; an example is shown in Figure 1B of Wintle (2008). This is in essence the technique that is used in single-aliquot dating, and it is described in more detail in that context below. In its most complete form, however, the multiple-aliquot regeneration method involves constructing both a regenerative dose–response curve and an additive-dose curve (Figure 3). The regenerative-dose data set is constructed so that it largely overlaps the additive-dose data set. If the initial laboratory bleach has caused no sensitivity change in the regenerative set of aliquots, then the dose response deduced from it should be identical to that found from the additive-dose aliquots. If this is the case, then the additive-dose data set is shifted along the dose axis so that it coincides with the regenerative data set, and a single curve is fitted to all the data (Figure 3). The magnitude of the shift is equal to the equivalent dose after corrections for incomplete laboratory bleaching and for the slight decay in OSL incurred during normalization (discussed

Figure 2 Example of the additive-dose with thermal-transfer correction (ADTT) method, as used for multiple-aliquot dating. The upper curve ($N + \gamma$ dose) is an additive-dose curve, while the lower curve ($N + \gamma$ dose + bleach) is used to correct for thermal transfer. Aliquots were irradiated with a ^{60}Co γ source in this case. The data shown is from the IRSL recorded during the first 5 s of stimulation. Both curves are extrapolated to where they intersect above the dose axis, and this point is taken as the dose-intercept value. Dose-intercept values are commonly determined as a function of stimulation time, and, if they are constant, an average value is usually taken as the equivalent dose, after small correction for the decay in luminescence (trapped electrons) that has resulted from the normalization procedure; see the text for additional detail. The data shown are from the violet (400 nm, 3.1 eV) luminescence emitted during the stimulation of the K-feldspar fraction in fine-silt polymineral aliquots with near-infrared (880 nm, 1.4 eV) light. IRSL was detected by an EMI 9365Q photomultiplier tube behind Schott BG-39 and Kopp 5–57 optical filters. The aliquots were preheated at 160 °C for 4 h before measurement. The sample is a 2.4 ka eolian deposit from south-central British Columbia, Canada (sample CCL4 of Lian and Huntley, 1999). Based on Figure 7 of Lian OB and Huntley DJ (1999) Optical dating studies of post-glacial aeolian deposits from the south-central interior of British Columbia, Canada. *Quaternary Science Reviews* 18: 1453–1466.

below). In practice, sensitivity change in the regenerative data set is identified by observing an intensity-scaling parameter in the curve-fitting algorithm. This regeneration method was introduced by Prescott et al. (1993) and is often referred to as the Australian slide method because of its extensive use in TL dating of a significant stranded beach dune sequence in southern Australia.

Normalization for Multiple-Aliquot Techniques

One of the drawbacks of the multiple-aliquot techniques is that the aliquots comprising a set can never be made to be identical. The reason for that is that a sample aliquot typically contains thousands of individual mineral grains, and these all have different OSL sensitivities. That is, for any given grain in a sample, the OSL emitted per dose of radiation is different, some grains emitting much more OSL than others. The OSL measured from an aliquot may, therefore, be dominated by that emitted from only a very small number of the grains. To compensate for this intrinsic difference between aliquots, all aliquots in a set are initially normalized. This is usually done

by recording the OSL intensity that results from a brief exposure to the stimulation beam (commonly referred to as a short shine) before the aliquots are given a laboratory dose. The severity of the short shine depends on the OSL intensity of the natural sample; if the affect of the short shine on the trapped electron population relevant to dating is significant, it can be accounted for when the equivalent dose is determined. Normalization factors are calculated for every aliquot by dividing the short-shine OSL intensity measured from them by the average short-shine OSL intensity of the entire set. These factors are used to reduce the scatter in the dose–response data.

Other normalization procedures include those for which the sample aliquots are given a short shine following a radiation dose and preheat that are administered after the final OSL measurements are made. These methods are used when the OSL intensities measured from the natural aliquots are too low, or if there is concern that the different laboratory doses (and the bleach treatment) administered to the various aliquots used to construct a sample's dose response have resulted in sensitivity change; a thorough discussion is given by Aitken (1998, p. 98). If the normalization factors are produced from the OSL measured from the natural aliquots, then the normalized dose–response data can also be used to give information on the degree of sunlight exposure a sample has experienced in the environment; this is discussed in detail by Huntley and Berger (1995) and Ollerhead et al. (2001).

Single-Aliquot Techniques

One of the advantages that optical dating has over TL dating is that only a small proportion of the relevant electron traps needs to be sampled to construct a dose–response curve. This was realized by Huntley et al. (1985) during the initial trials of optical dating and they suggested that a sample's dose response could be constructed from just a single aliquot of prepared sediment. This prompted other workers to develop techniques that required only one or two aliquots of a sample to estimate equivalent dose. Indeed, one can now calculate an optical age value from a single grain of sand. The main advantage of this is that it is possible to determine the desired optical age value of a sample (which usually is its burial age) which consists of grains that belong to different equivalent-dose populations. Moreover, since all the measurements are performed on a single aliquot, normalization is not required. All the single-aliquot methods described below therefore involve repeatedly preheating, stimulating (with light), and dosing the same sample aliquot.

The first single-aliquot protocols were developed in the early 1990s (e.g., Duller, 1991) and involved constructing an additive-dose curve for a sample, and extrapolating it to the dose axis. These single-aliquot additive-dose (SAAD) techniques were followed by the single-aliquot regeneration and added dose (SARA) method where the natural OSL is plotted on a regenerative-dose curve and the place where this point intersects the dose axis is taken to be the equivalent dose. In reality, these early single-aliquot protocols were not truly single aliquot as at least one additional aliquot is required to correct for the progressive loss of OSL signal and (or) to monitor sensitivity change. In the use of additional aliquots it is presumed, as with the multiple-aliquot techniques, that all the

Figure 3 Illustration of the Australian slide method, a combined additive- and regenerative-dose method used for determining equivalent dose; it is especially useful in cases where extrapolation of the additive-dose curve to the dose axis is large. The data in (a) are the additive-dose data ($N + \beta$ dose), while the data shown in (b) are those from aliquots that have received an extended exposure to light before being given various laboratory doses of radiation – the regenerative-dose data set ($N + \text{bleach} + \beta$ dose). Irradiation was from a $^{90}\text{Sr}/^{90}\text{Y}$ β source in this case. The aliquots were preheated at 140 °C for 7 days before measurement. The additive-dose data are shifted along the dose axis until they coincide with the regenerative data, the magnitude of the shift being equal to the equivalent dose, after a correction for incomplete laboratory bleaching and for decay of the OSL signal (trapped electrons) incurred during normalization. If there has been no sensitivity change in the regenerative data, then both data sets should define the same curve. The data shown is from lacustrine sediment from Lake Poukawa, New Zealand, that gave an apparent optical age of 83 ± 7 ka (sample LPCS22 of [Shane et al., 2002](#)). The mineral type and size, and the measurement conditions, are the same as those described in [Figure 2](#), except in this case the photomultiplier tube was an EMI 9235QA, and a Kopp 5–58 filter was used instead of a Kopp 5–57 filter.

grains in a sample have had the same bleaching history and have the same OSL sensitivity. For that reason, the SARA technique has become limited to heated materials. Reviews of the early single-aliquot methods can be found in [Aitken \(1998\)](#).

The SAAD method was later modified so that it required only one aliquot, but the problem of sensitivity change due to repeated preheating and measurement remained. This led to the development of the single-aliquot regenerative-dose (SAR) technique, which incorporated a method for correcting for the sensitivity change. The first SAR protocols monitored sensitivity change by observing the response of the 110 °C TL glow-curve peak during preheating, but this practice was eventually

replaced by observing a sample's OSL response to a small radiation dose (a so-called test dose) that is administered at the end of each regenerative-dose cycle (e.g., [Murray and Wintle, 2000, 2003](#); [Roberts et al., 1998](#)). The SAR protocol described by [Murray and Wintle \(2000, 2003\)](#) and [Wintle and Murray \(2006\)](#), or some slight modification of it, currently is the method favored by most optical dating practitioners; it is illustrated, with additional detail, in [Figure 4](#). At present the protocol is used almost exclusively to date quartz as it has been found to be inadequate for correcting for sensitivity change in feldspar (e.g., [Blair et al., 2005](#)), but there have been several cases where it has been shown to be applicable

Figure 4 Example of the basic single-aliquot regenerative-dose (SAR) method of Murray and Wintle (2000). The procedure, based on that described in Table 1 of Murray and Wintle (2000), is shown in (a): For the natural sample, $i = 0$ and $D_0 = 0$ Gy. The OSL used for regenerative-dose data points (L_i), and the OSL measured from the test doses (T_i), typically are derived from that measured during the first second or less of stimulation thereby selecting the thermally stable fast component of the shine-down curve (although longer intervals are sometimes used), minus the OSL measured from the last part of the shine-down curve (the late-light). An alternative approach is to deduce L_i by subtracting from the initial luminescence signal the so-called early light instead of the late-light, the early light usually being that which is measured during an interval immediately following that used for the initial measurement. The intention of the early-light subtraction method is to minimize the influence of the OSL measured from the malign slow and medium components of the shine-down curve that are found in quartz. This method has shown success in some cases (e.g., Ballarini et al., 2007; Cunningham and Wallinga, 2010; Pawley et al., 2010), but it should still be considered novel and it therefore should be applied with due vigilance. An alternate approach to isolating the fast component is to apply curve stripping algorithms (e.g., Bailey et al., 1997), but mathematically deconvoluting overlapping exponential (shine-down) curves can be difficult (Bailey, 2010). Another method that is intended to isolate the thermally stable, and fast, OSL component in quartz from malign components involves stimulating the sample while at an elevated temperature with infrared (IR) light instead of blue light. For this method to be effective the sample has to be relatively bright and be free of feldspar contamination as quartz responds poorly to IR light; a thorough review of this novel approach is provided by Bailey (2010). In general, during standard quartz OSL measurement (i.e., with blue-light

also to this mineral (e.g., Banerjee et al., 2001; Davids et al., 2010; Lamothe, 2004; Steffen et al., 2009a). Single-aliquot techniques, like SAR, are not immune to thermal transfer resulting from preheating, but its effect on equivalent dose can be monitored by repeating the experiments using increasing preheat temperatures (this practice is sometimes called a preheat-plateau test). Moreover, its effect can also be monitored by observing the OSL intensity measured from a zero-dose point on the regeneration curve (the so-called recuperation test). Unfortunately, if thermal transfer is significant in a sample, and cannot be made tolerable by reducing the preheat temperature or by adding (for quartz) a high-temperature blue-light stimulation step at the end of each cycle (Figure 4), then the sample cannot be dated using SAR.

The success of the test-dose procedure for correcting sensitivity change is assessed by repeating at least one of the data points on the regenerative-dose curve (the so-called recycling test), and a dose recovery test is required. For the latter, fresh aliquots (naturals) are bleached so that essentially all of the relevant electron traps are emptied. These aliquots are then all given a laboratory radiation dose that is similar to the sample's equivalent dose, and then an attempt is made to recover the laboratory

stimulation and detection in the ultraviolet), the sample aliquots are held at 125 °C to prevent the re trapping of electrons in the 110 °C TL trap; the aliquots are allowed to cool to <60 °C before the next step in the SAR cycle. The preheat treatment that is given after the test dose is administered (step 5) is commonly less severe than that given after a regenerative dose so as not to induce additional sensitivity change: what is usually done for this test-dose preheat is that the temperature of the aliquot is increased to 160 °C and then the heat is abruptly turned off (a so-called cut-heat treatment). Other steps may be included in the SAR routine as well, such as a short stimulation with IR light to check for feldspar contamination in a quartz sample, or a longer stimulation with IR light to attempt to 'wash' away the unwanted feldspar signal (Olley et al., 2004), or the addition of a high-temperature preheat (e.g., 280 °C), while the aliquot is stimulated with blue light at the end of each cycle to reduce the effect of thermal transfer (Murray and Wintle, 2003). Whether or not these added treatments are successful depends to a large degree on the characteristics of the sample. (b) Example of SAR shine-down curves, and the corresponding regenerative-dose graph (inset), for a quartz sand sample. Modified from Figure 7 of Lian OB and Roberts RG (2006) *Dating the Quaternary: Progress in luminescence dating of sediments. Quaternary Science Reviews* 25: 2449–2468. The quartz sample in this example is from Lake Mungo, Australia (sample M3T 58.0 m of Bowler et al. (2003)), and it yielded an optical age of 42.2 ± 2.5 ka. For the regenerative-dose graph, the units on vertical scale are arbitrary (dimensionless) because they are derived from the ratio L_i/T_i , where T_i is used to correct for sensitivity change in L_i . Of special importance in this example is that the duplicate dose point of 15 Gy on the regenerative-dose graph has a so-called recycling ratio (1.06 ± 0.03) that is consistent with unity, indicating that the test-dose procedure intended to correct for sensitivity change has been successful. Also of importance is that the intensity of the zero-dose measurement is only 1.6% of the intensity of the OSL measured from the natural aliquot indicating that thermal transfer as the result of the preheat (220 °C for 10 s in this case) is tolerable. The aliquot was stimulated for 100 s with blue (470 nm, 2.6 eV) light from an LED array, with the diodes set at constant intensity. The ultraviolet (350 nm, 3.6 eV) OSL signal, recorded by an Electron Tubes Ltd. 9235QA photomultiplier tube mounted behind a Hoya U-340 optical filter, used for construction of the regenerative-dose curve consisted of that measured during the first 3 s of stimulation, minus that recorded during the final 30 s.

dose using the same SAR protocol that was used to determine the equivalent dose of the natural sample. That a sample pass these tests (recuperation, recycling, and dose recovery) is a necessary, but unfortunately not a sufficient, condition for a calculated age value to be accepted (e.g., see Steffen et al., 2009a).

Optical Dating Using Linear Modulation

In the vast majority of cases, it is desired to sample the most light-sensitive electron traps – in other words, those that are responsible for the OSL recorded at the beginning of a shine-down curve (i.e., that from the so-called fast component of a shine-down curve, which was discussed earlier). In practice, therefore, one typically constructs a sample's dose response from the OSL recorded in the first second (or less) of continuous wave (CW) stimulation. What is meant by CW is that OSL is recorded while the stimulating light source is held on a sample at constant power. An alternative way of recording OSL is to do so while ramping the power of the stimulating light source at the sample from zero to some maximum value. This measurement technique is referred to as linear modulation (LM; Bulur, 1996). Using LM one can separate and record the various decay components that make up a shine-down curve (Figure 5). For example, the fast or most slowly bleaching components can be separated, and dose-response curves can be constructed from each. This is significant as there are samples for which a fast component is missing or is too dim to be used for dating, and there are other situations where the measurement of a slow component might be desired over a fast one.

Optical Dating Using Pulsed Stimulation

When a mineral sample is exposed to the stimulation beam there is a small delay before the resulting OSL is emitted; this is referred to as the luminescence lifetime. Because the luminescence lifetime is different for quartz and feldspar, it is possible to use pulsed stimulation to discriminate between the OSL arising from these two minerals in unseparated samples. For feldspar most of the OSL is emitted in a few μs after the stimulating pulse is switched off, whereas for quartz it persists for much longer ($>100\ \mu\text{s}$); see Figure 4 in Denby et al. (2006). In practice, the OSL that is used to construct the dose response is measured in the time between the pulses of stimulating light. Technical details and tests of the method can be found in Denby et al. (2006), Thomsen et al. (2008b), and Niedermayer and Bayer (2010).

Analysis and Presentation of Equivalent-Dose Distributions Arising from Single-Aliquot Techniques

As mentioned above, the main advantage that the single-aliquot techniques have over the multiple-aliquot methods is that an equivalent dose value can be determined from a very small aliquot of sample, even from just a single grain of sand, and this has led to the possibility of deducing the true age of a sedimentary deposit even if it consists of grains with different bleaching histories (i.e., different optical age values). In practice, current instrumentation and analytical software allows for hundreds of equivalent-dose values to be efficiently determined from less than a gram of prepared sediment. The challenge,

Figure 5 Example of linear modulation (LM) response curves for four individual sand-sized grains of quartz (naturals) extracted from the sample discussed in Figure 4(b). In each case, stimulation was from a focused green (532 nm, 2.3 eV) semiconductor laser, for which the intensity of the beam was steadily increased from zero to 90% of its maximum value (i.e., the laser power at the grain was ramped from 0 to 45 mW cm^{-2}) over a period of 30 s. Curve (A) consists of the background counts from the photomultiplier tube, while curve (B) is the LM-OSL from a grain that consists of more than one OSL component – in other words, the grain contains more than one population of electron trap, each population having a different sensitivity to light. The curve (C) is from a grain dominated by the so-called fast component, while curves (D) and (E) are LM-OSL data from grains dominated by the medium and slow components, respectively. Curve (C) has been multiplied by a factor 0.2 for the purpose of clarity of presentation. For this particular sample, the total LM-OSL output for a collection of grains over the first 5 s of stimulation is dominated by that from grains with an intense fast component, with 55% of the standardized estimate measured OSL coming from just 10% of the grains. The data are from Bowler et al. (2003). Modified from Figure 7 of Lian OB and Roberts RG (2006) Dating the Quaternary: Progress in luminescence dating of sediments. *Quaternary Science Reviews* 25: 2449–2468.

therefore, has been to analyze a distribution of equivalent-dose values and determine the desired equivalent dose and optical age from it. In reality, the spread in equivalent-dose values observed in a single sample is not only a result of its bleaching history, but also comes from differences in local dosimetry and variations in the intrinsic sensitivity of the grain(s) that make up an aliquot. Indeed, even samples that consist of grains that initially had all received extended sunlight exposure can show a spread in equivalent-dose values that is beyond that associated with analytical uncertainties. The cause of this so-called overdispersion is not fully understood.

Several methods have been devised to analyze equivalent-dose distributions, but the most useful arguably are those described by Galbraith *et al.* (1999). The models proposed by Galbraith are based on well-established statistical principles and are applicable to samples from a broad range of depositional environments: one of these statistical models is the central age model (CAM), which determines the equivalent dose from the weighted mean value, and takes into account overdispersion. Another is the minimum age model (MAM), which estimates the equivalent dose of a sample using the lowest equivalent-dose values; this approach has been validated in simulations on young fluvial sediments. The finite mixture model (FMM; Galbraith, 2005; Roberts *et al.*, 2000) can be applied in cases where a sample consists of grains belonging to two or more equivalent-dose populations. The FMM allows the number of equivalent-dose components to be estimated and ages can then be calculated from each one (e.g., Jacobs *et al.*, 2008). However, the FMM has been found to be applicable only in cases where each aliquot consists of a single grain of sand (Arnold and Roberts, 2009).

Statistical models should not be used blindly. Some prior information about the depositional environment that a sample came from is needed. For example, it is unlikely that the MAM should be used to date a loess deposit, or, for example, that the CAM should be applied to sediment extracted from poorly bleached alluvium. Clearly, information from a detailed sedimentological investigation is needed to help make a decision about what statistical model is most appropriate for the situation at hand. Indeed, Bailey and Arnold (2006) demonstrated through modeling that no one method of analysis is suited to all depositional environments, but that it is possible to select the most suitable method on the basis of the shape of the equivalent-dose distribution.

The method by which an equivalent-dose distribution is presented is also of importance. Basic histograms, as in Figure 6, were used initially but these do not show the variation in precision between aliquots that arise due to counting statistics – that is, equivalent-dose values calculated from highly luminescent (bright) aliquots being more precise than those determined from dim aliquots. The best graphical representation of equivalent-dose distributions probably is the radial plot (Galbraith, 2010; Galbraith *et al.*, 1999) in which the precision associated with each equivalent-dose value is clearly represented (Figure 6), and the degree of overdispersion can be evaluated. Weighted histograms and probability density plots may alleviate the problems associated with conventional histograms and probability density plots but they can be difficult to interpret. Berger (2010) has suggested that if probability

Figure 6 (a) Histogram showing the frequency distribution of the equivalent-dose values determined from 86 single quartz grains. The sample and the measurement conditions are the same as those discussed in Figures 4 and 5. (b) Radial plot of the same data shown in (a), where the horizontal shaded band represents the weighted-mean equivalent-dose value of all the data, which is 15.3 Gy. The histogram in (a) shows several equivalent-dose values >20 Gy, some which have poor precision, an aspect not represented in this kind of representation. The radial plot in (b), however, displays these data along with their precision, the more precise data plotting further away from the origin (center of the circle). For this sample, grains with relative errors of <1% (i.e., a precision value >100) have equivalent-dose values that are distributed over a range of 14–18 Gy. Also of note in this radial plot are the relatively high number of equivalent-dose values that fall outside the gray band. This gives a visual indication of the degree of overdispersion (see text) in this sample. Reproduced from Figure 8 of Lian OB and Roberts RG (2006) *Dating the Quaternary: Progress in luminescence dating of sediments. Quaternary Science Reviews* 25: 2449–2468.

density plots are desired, then the use of such plots with log-transformed equivalent-dose values and relative error estimates can further overcome the shortcomings of their conventional counterparts.

Sample Collection and Preparation, and Quartz or Feldspar?

Although sample collection for optical dating is relatively simple, it should be done by someone from the dating laboratory, together with a geoscientist familiar with the sedimentology (i.e., inferred depositional processes) of the sample site and the environmental history of the region, so that the best sampling strategy can be established. Sample collection and laboratory preparation are summarized elsewhere in this encyclopedia, while more detailed accounts can be found in Wintle (1997), Aitken (1985, 1998), and Lian and Huntley (2001); Lian et al. (1995) discuss cases where organic content is significant.

Whether quartz or feldspar is used for dating depends on the relative abundance of these minerals in a sample in the desired grain size, as well as the luminescence characteristics of the mineral which can be, to some degree, specific to the sample. The main advantages and disadvantages of using quartz and feldspar for optical dating are summarized in Figure 7 and are discussed in more detail by Wintle (2008).

Environments Suitable for Optical Dating

Any sedimentary deposit that contains an adequate amount of quartz and/or potassium feldspar grains in the desired size fraction, which have been exposed to sufficient sunlight or heat prior to final burial, has the potential for yielding an accurate optical age. As with TL dating, the most suitable environments are those in which the sediment has been transported over considerable distances in the atmosphere and/or have been reworked by other processes at the ground surface for an extensive amount of time before finally being buried and shielded from sunlight. Much of optical dating of sediments therefore has been done on eolian deposits such as loess and dune sediment. However, the greater sensitivity to sunlight of the electron traps responsible for OSL, compared to that of the traps responsible for TL, has resulted in the application of optical dating to a greater variety of depositional environments. Moreover, the development of single-aliquot techniques (especially SAR) has introduced the possibility of extracting the true burial age of a sediment from a deposit consisting of grains with different bleaching histories (i.e., with various age populations).

Examples that illustrate all of the applications of optical dating are too numerous and varied to be adequately discussed here, and the reader is directed to the published proceedings of the International Luminescence and Electron Spin Resonance Dating (LED) Conferences, where recent case studies and new developments are concisely presented. The two most current LED conference publications can be found in the journals *Quaternary Geochronology* (2(1–4), 2007; 5(2–3), 2010) and *Radiation Measurements* (41(7–8), 2006; 44(5–6), 2009). The journal *Ancient TL* (free online at: www.aber.ac.uk/ancient-tl/) publishes short articles on the experimental and theoretical aspects of optical dating; *Ancient TL* also includes papers related to TL and ESR dating. Illustrative examples can also be found in Prescott and Robertson (1997), Roberts (1997), Aitken (1998), Wagner (1998), Walker (2005), and Lian and

Roberts (2006) and in the special issue of the journal *Boreas*, 'Luminescence dating of Quaternary sediments' (35(4), 2008). Some examples that illustrate the diverse application, and the current age range, of optical dating are given below.

As mentioned above, one of the advantages that optical dating has over TL dating is that the electron traps responsible for the optical signal are much more sensitive to light, compared to those responsible for TL. This has allowed samples to be dated using OSL that are much younger than those assessable using TL. For example, Smith et al. (1990), using quartz, green laser light for stimulation, and the multiple-aliquot additive-dose method, were able to produce optical ages of 46 ± 30 , 95 ± 14 , and 350 ± 110 years, for eolian dune sand in Mali and France. More recently, Wolfe et al. (2002), using K-feldspar sand, infrared (IR) stimulation, and the multiple-aliquot ADTT technique, produced optical ages as young as a few decades with analytical uncertainties $<15\%$ (at two standard deviations) for eolian dune sands from the Canadian prairies. These optical ages agreed well with expected ages.

Huntley et al. (1993) demonstrated that IR stimulation could be used to preferentially stimulate K-feldspar inclusions in quartz grains. These workers used the multiple-aliquot ADTT method and quartz sand sampled from the stranded beach dune system in South Australia, and produced optical ages up to 400 ka that matched well with independent age information. Lian et al. (1995), on the other hand, used the multiple-aliquot ADTT protocol and IR stimulation to selectively date the K-feldspar grains in polymineral silt-sized samples extracted from peat deposits, and found good agreement between the optical ages and independent age information for samples ranging in age from 0 to ~ 120 ka once corrections for organic content was incorporated into the dose-rate calculations.

Examples of using OSL to date heated sediments include that of Lang and Wagner (1996), who successfully dated the fine-silt fraction of alluvium in southwestern Germany that was interpreted to have been heated by a campfire during the Roman period. The mineral of choice in this case was K-feldspar, which was stimulated by IR light. Equivalent doses, and optical ages, were determined using the multiple-aliquot additive-dose with late-light subtraction technique. Another example of dating fired sediment is provided by Lian and Brooks (2004) who sampled heat-altered alluvial mud from the base of small hearths in southern Manitoba (Canada) thought to be of anthropogenic origin. These workers also selected K-feldspar in the fine-silt polymineral fraction by selectively stimulating it with IR light. Optical ages were calculated from equivalent doses found using the multiple-aliquot ADTT method. These optical ages were consistent with accelerator mass spectrometry (AMS) radiocarbon ages of charcoal fragments found in the heated sediments, which dated the hearths to about 1 ka. A similar study was completed by Fu et al. (2010) who found consistency between quartz-based SAR ages of heated and light-exposed sediments (~ 5 ka) at an archaeological site at Qujialing, China.

One of the most novel applications of a single-aliquot protocol was provided by Roberts et al. (1997) who sampled quartz grains from relict mud wasp nests covering prehistoric paintings on cave walls in the Kimberly region of northern Australia. The premise was that wasps had previously collected

Quartz		Feldspar	
Advantages	Disadvantages	Advantages	Disadvantages
Highly resistant to weathering	Relatively low OSL intensity; some quartz samples do not emit measurable OSL; signal may consist of thermally unstable components	OSL saturates at higher radiation doses than does that from quartz	Weathers more readily from the environment than does quartz
OSL signal bleaches more rapidly in sunlight than that from feldspar	OSL saturates at lower radiation doses compared to that emitted from feldspar	OSL intensity may be orders of magnitude higher than that emitted from quartz	Suffers from anomalous fading
Does not appear to suffer from anomalous fading	Thermal transfer can be higher in quartz than in feldspar	IRSL can be stimulated preferentially in unseparated mineral mixtures (polyminerall samples)	Difficult or impossible to correct for sensitivity change in regenerative-dose data when using SAR

(a)

(b)

Figure 7 (a) Summary of the principal advantages and disadvantages of using quartz or K-feldspar for optical dating. The fact that the IRSL emitted from K-feldspar typically saturates at higher radiation doses than that emitted from quartz, and because the luminescence emitted from K-feldspar is usually much more intense than that emitted from quartz, and that the K-feldspar IRSL signal does not appear to include malign components as does that of some quartz samples, makes feldspar ideal for dating both very young and very old samples. Feldspar, however, suffers from anomalous fading where quartz appears not to. It is mainly for that reason that quartz is used more widely than feldspar when both minerals are present at a sample site. Anomalous fading was first observed in feldspar by Wintle (1973) and refers to the loss of electrons from traps that are expected to be thermally stable and ambient temperatures over geological time, to other defects and centers in the crystal lattice; it is thought that quantum-mechanical tunneling is the mechanism responsible for this phenomenon. Some studies have suggested that alkali feldspars (K-feldspars) exhibit less anomalous fading than does most plagioclase feldspars (but see below), and this is one of the reasons that the former feldspar mineral has been preferred over the latter for optical dating. Experiments using the dominate IR-stimulated violet emission (centered at 400 nm, 3.1 eV) from a variety of sand-sized K-feldspar natural sediment samples, and from small slices taken from whole K-feldspar crystals, collected from various parts of the world (80 samples in total), have strongly suggested that anomalous fading is ubiquitous in this mineral (Huntley and Lamothe, 2001; Huntley and Lian, 2006). It has also been observed that plagioclase feldspar with low Ca content show no tunneling (fading), and that such minerals may be used to extend the current upper age limit of optical dating (Huntley et al., 2007). For sufficiently bright feldspar samples, anomalous fading can be measured in the laboratory with the necessary precision, and if its magnitude is significant, then either it must be corrected for or the sample cannot be dated. Huntley and Lamothe (2001) devised a way to correct for anomalous fading by using a sample's measured fading rate, but their technique only can be applied to a sample that is in the linear part of its dose response. It has been observed, however, that the 400 nm IR-stimulated luminescence from fine-silt sized K-feldspar can often yield optical ages that are in good agreement with independent age information without correction for anomalous fading. This suggests that, for some samples, grain size, or perhaps the mineral's resistance to weathering, might be a factor affecting the degree of anomalous fading in a sample. Other studies have indicated that using various preheat protocols, or by sharply blocking the luminescence emitted at wavelengths below 400 nm, will reduce anomalous fading to a point where it can be tolerated (e.g., see discussion in Berger et al., 2004), and it has also been shown that the 400 nm emission from K-feldspar measured while the sample is held at a temperature of 220 °C shows reduced anomalous fading, if this measurement is preceded by an infrared wash at low temperature (~50 °C; Buylaert et al., 2009, 2012; Thomsen et al., 2008c).

(b) Comparison of the effectiveness of direct sunlight in emptying the traps in quartz and feldspar responsible for OSL and TL (reproduced from Godfrey-Smith DJ, Huntley DJ, and Chen W-H (1988) Optical dating studies of quartz and feldspar sediment extracts. *Quaternary Science Reviews* 7: 373–380). The TL data are from the 310–320 °C range, while the OSL data are that from the first 20 s of stimulation, using green (514 nm, 2.4 eV) photons from an argon ion laser. Note that the OSL signal from quartz bleaches faster than that from feldspar, and much faster than the TL signals from both minerals. The quartz was from a 500-ka eolian dune sand, while the feldspar was from a 70-ka fluvial sand.

mud (containing quartz sand grains) from well-bleached surfaces distant to the cave mouth, and that the luminescence clock had started after the grains had been deposited on the cave wall and covered by a subsequent nest layer(s). These workers, using a SAAD method, showed that at least some of the cave paintings must have been constructed before 17 ka. A somewhat similar study was undertaken by Baran et al. (2003), but in this case the features of interest were prehistoric stone structures in southern Sweden. Baran et al. sampled sediment that had been used to fill the spaces between the stones, extracted quartz sand-sized grains from it, and applied the SAR protocol (Murray and Wintle, 2000) to small aliquots and single quartz grains, and deduced that construction of the stone structures had probably commenced as early as 7 ka.

The advent of single-grain dating has opened up the possibility of analyzing the character of the dose responses associated with individual grains. Yoshida et al. (2000) looked at the dose responses of single grains of quartz from samples ranging in age from ~250 to ~950 ka collected from the well-studied stranded beach dune system in South Australia. They found that all but one of the nine samples studied contained a small number of grains (~15%) that were strongly luminescent, and whose luminescence signal saturated at unusually high laboratory radiation doses. Some of these grains yielded ages approaching 1 Ma that were consistent with the independent chronology of the dunes. A similar approach has been used by Rhodes et al. (2006) to date marine sands and eolian deposits, some approaching 1 Ma, associated with archaeological material in northwestern Africa. A relatively new approach that has the potential to extend the upper age limit of optical dating even further was introduced by Rink et al. (2007). This method involves measuring the light-sensitive defects associated with aluminum and titanium atoms on silicon sites in quartz using ESR. This new method is referred to as ESR optical dating, and it is thought to have the potential to date samples that were last exposed to an extended period of sunlight 5 Ma ago or more (Rink et al., 2007).

A good example of the use of the LM technique is that of Olley et al. (2006) who used this technique to show that grains incased in resin-impregnated sample blocks, that held grave-infill sediments associated with ancient human fossils, had been sufficiently protected from room light exposure while being archived in a laboratory. First, these workers applied the SAR protocol to single quartz grains, and used the fast component of the continuous-wave OSL shine-down curve, together with the maximum age model, to produce equivalent-dose values (and optical ages) which were consistent with the expected age for sediments. They then applied the LM technique to grains from the same sample and found that both the fast and slow components produced equivalent-dose values that were consistent with each other. This confirmed that the grains had remained sheltered from light during storage. A similar approach had previously been used by Yoshida to date archaeological samples, and by Olley to investigate deep-sea sediments (see Lian and Roberts, 2006).

Factors that can Lead to an Inaccurate Optical Age

The most significant factor that can lead to an inaccurate optical age is that the mineral grains comprising a sample

collected from a sedimentary deposit have not all been exposed to sufficient sunlight, or heat, prior to burial. If this is the case, and if multiple-aliquot techniques are used, the calculated optical age will either represent the true age of the deposit, or it will lie somewhere between the true age and the apparent age of its parent material(s), although some information about equivalent-dose (age) populations can be gained from studying the scatter in the normalized dose-response data (e.g., Ollerhead et al., 2001). If single-aliquot methods are used, it is much easier to identify equivalent-dose distributions, and in many cases the equivalent dose representing the event of interest (e.g., the time elapsed since burial) can be extracted from it.

An inaccurate or unacceptably imprecise optical age can also result (1) if an inappropriate laboratory protocol is chosen for determination of the equivalent dose, (2) if an inappropriate curve is fitted to the dose-response data, (3) if there is, or has been, significant radioactive disequilibrium at the sample site, and (4) if single grains are dated and variations in microdosimetry are significant.

More complex phenomena that can cause problems are (1) thermal transfer that cannot be corrected for, (2) sensitivity change that cannot be detected (as can occur when using multiple-aliquot techniques) or corrected for (when using single-aliquot methods), (3) the failure of a dose recovery test in single-aliquot dating, (4) overdispersion in equivalent-dose values found using single-aliquot techniques that is not recognized or is not accounted for, and (5) if OSL from a part of the shine-down curve that represents electron traps that are difficult to bleach, or are thermally unstable (the so-called medium and slow components), is used to construct the dose response (e.g., Steffen et al., 2009b).

If feldspars are dated, the severity of anomalous fading has to be assessed, and if it is significant, it has to be avoided or corrected for, as discussed in Figure 7. In light of all these potential pitfalls, it is highly advisable, when using any of the optical dating protocols, no matter how well established, to date at least one sample from the sedimentary sequence or landform of interest for which the age has previously been determined by an independent, and reliable, method.

Introduction

Electron spin resonance (ESR), also called electron paramagnetic resonance, is a dating technique based on the accumulation of free electrons or holes (electron defects) in the crystal lattices of minerals. The process is due to exposure to radiation emitted from radioactive nuclides in the sample and its environment. Hence, it is a 'radiation-dose' or 'trapped-charge' method, similar to thermoluminescence (TL) and optically stimulated luminescence (OSL). These methods differ in the instrumentation used and the physical processes involved in the accumulated radiation dose.

In ESR, the mineral accumulates radiation damage and acts as a kind of dosimeter of its total exposure to radiation from the surrounding environment, and the sample itself. An ESR age is derived from the measurements of the dose that the sample has received over time. The most common applications of this method are to tooth enamel, corals, mollusk shells, and quartz.

Basic Principles

There are two energy levels at which electrons may exist: the ground state (valence band) and a higher energy state (conduction band). These are shown schematically in Figure 1. In insulators, such as quartz, feldspar, apatite, and calcite, the two energy bands are separated by energy levels that are forbidden transitions from the ground state. Naturally occurring radionuclides emit a variety of radiation, for example, α -particles (He nuclei), β -particles (electrons), and γ -radiation (photons). When these particles interact with matter, electrons in the atoms can be excited from the valence band to the conduction band, and electron defects ('holes') accumulate in the valence band. In general, these holes are rapidly filled by other electrons. However, electrons (and holes) can also become trapped in intermediate energy levels where they cannot decay back to the ground state. All minerals contain such defect sites where electrons and holes can become trapped (Figure 1). When the sample is initially crystallized, it should not contain any defects, and the ESR signal should be zero. After formation, the mineral is exposed to radiation, leading to the accumulation of the electronic defects. These trapped electrons and holes form paramagnetic centers, since there are unpaired electrons present. Paramagnetic centers show weak magnetic response in an applied magnetic field, which can be detected with an ESR spectrometer, giving rise to a characteristic resonance (Figure 2).

In addition to the accumulation of electronic defects, ESR signals can arise from the breaking of covalent bonds to form free radicals, such as CO_2^- (an ionized free radical) from

carbonate ions. This is the most common process for trapped-charge accumulation in secondary carbonates such as speleothems, shells, and corals, as well as tooth enamel. Grün et al. (2008) noted that CO_2^- can occur in two forms with different symmetries, leading to a small difference in the ESR signal and additional errors of <5%. Later, Joannes-Boyau and Grün (2011) showed that these differences could account for the underestimation of ages by up to 30%.

The measured ESR signal is called the 'natural intensity' and is dependent on the number of traps or radiation dose (D), the dose rate of the radioactivity (dD/dt), and the radiation time T , which should be the age of the sample. The product of dose rate and time is the equivalent dose D_e that the sample has received in the past. Hence,

$$D_e = \int_0^T D(t) dt \quad [1]$$

If dD/dt is a constant, this equation integrates to

$$T = D_e / (dD/dt) \quad [2]$$

The determination of the D_e value is the ESR part of the procedure. It is necessary to separately evaluate the radiation dose from analysis of radioactive elements (mainly Th, U, and K) from the sample and its surroundings. We will discuss this later.

Measurement of the Dose Value

D_e is the equivalent dose and is derived from the fact that laboratory sources use γ -rays whereas the accumulated dose is the sum of different energies of α -, β -, and γ -radiation. Thus, the experimentally determined dose value is the γ equivalent of the naturally received dose, which is frequently called the paleodose P . The SI unit for absorbed radiation dose is the gray (Gy), which is equivalent to the deposition of one joule of energy (J) in 1 kg of matter.

In order to produce reliable results, the measured ESR signals must have the following properties:

- The signal intensity increases in proportion to the received dose.
- The signals are thermally stable, to at least an order of magnitude longer than the age of the sample.
- The number of traps is consistent in the material. Recrystallization, crystal growth, or phase transformations should not have occurred.
- The signal does not show anomalous fading.
- The signals are not influenced by sample preparation, such as grinding, exposure to laboratory light, etc.

Figure 1 Trapping of electrons and holes, which is the basis for electron spin resonance (ESR) dating. An insulating mineral has two energy levels at which electrons may exist. The lower energy level (valence band) is separated from the higher energy level (conduction band) by a so-called forbidden zone. When a mineral is formed or reset, all electrons are in the ground state. Ionizing radiation emitted from radioactive elements (U, Th, and K) removes negatively charged electrons from atoms. The electrons are transferred to the conduction band, and positively charged holes are left behind near the valence band. After a short time of diffusion, most of the electrons recombine with the holes. Some electrons can be trapped by impurities (electron traps) in the crystal lattice. These unpaired (free) electrons can be directly measured by ESR spectroscopy. E_a is the activation energy or trap depth.

Two processes limit the applicability of ESR for dating:

Saturation: When all the available traps are filled, any further irradiation does not result in further formation of paramagnetic centers. In high-dose-rate environments, saturation may occur within a short period (a few thousand years), whereas in low-dose environments, this may occur in a few million years.

Thermal stability: Trapped electrons have only a limited probability of remaining in the traps. After a mean lifetime (τ), ~64% of the electrons will have left the trapped and returned to the ground state. The effects of 'fading' (loss of the ESR signal) can be neglected only if the lifetime τ is about ten times longer than the sample age. The thermal stability of different paramagnetic centers may be different.

It is not possible to give a general upper limit for ESR dating because of the dependence of both saturation and thermal stability on the specific nature of the paramagnetic centers and the environment of the samples. Each case needs to be evaluated individually. On the younger end of the dating scale, ESR measurements on tooth enamel have been used in evaluating small doses that would naturally accumulate in a few hundred years. Similarly, good ESR results have been obtained

Figure 2 ESR spectra of tooth enamel. The spectrum is dominated by a CO_2^- radical (a). Some spectra show interferences by methyl (* in (b)), SO_2 (+), and a rotating CO_2^- (#).

on shell and coral samples of a few hundred years' age. At the other end of the timescale, EST analysis of tooth enamel has provided reasonable results over 2 million years (Curnoe et al., 2001; Schwarcz et al., 1994). Corals and shells produce systematic underestimates older than about 300 000 years as a result of the limited thermal stability of this ESR signal.

For measurement of the D_e value, the sample is irradiated in the laboratory with increasing doses from a calibrated γ -ray source. This irradiation produces more paramagnetic centers and a consequent increased ESR signal. A dose-response curve can be established by plotting the ESR signal intensity against the applied dose (Figure 3). The data produced can be extrapolated to zero intensity, and the D_e value results from the intercept of the plot with the x -axis. In contrast to luminescence studies, it is not usually possible to regenerate the ESR signal in the way that can be often done in TL and OSL, because heating often changes the ESR characteristics of the minerals. The dose-response curve is not necessarily linear because of the saturated effects of different paramagnetic centers.

ESR Measurement

ESR intensities can be measured with off-the-shelf instrumentation (manufactured by Bruker, JEOL, and Varian, for example). An ESR spectrometer has three basic components (Figure 4(a)): a strong electromagnet, a microwave generator (either a Gunn diode or klystron), and an electronic data-processing unit. The sample is located in a cavity between the poles of the magnet. The cavity is connected to the microwave generator by waveguides. The paramagnetic centers have

Figure 3 Dose (D_e) determination using the additive dose method. After measurement of the natural intensity, the sample is irradiated in the laboratory. This leads to the production of more paramagnetic centers (see [Figure 1](#)). Consequently, the signal intensity increases. The plot of ESR intensity versus laboratory dose is called the dose–response curve. The D_e value results from fitting the data points of the dose–response with an exponential function and extrapolation to zero ESR intensity.

permanent magnetic moments (μ_s) due to the spin of the unpaired electrons. In an external magnetic field, this magnetic moment has two energy states: the ground state, when the spin is oriented toward the magnetic field direction; and an excited state, when the spin is in the opposite direction ([Figure 4\(b\)](#)). The difference between these two energy levels, ΔE , can be expressed as

$$\Delta E = g\mu_B H \quad [3]$$

where g is the Landé factor, μ_B is the Bohr magneton ($9.274078 \times 10^{-24} \text{ J T}^{-1}$), and H is the magnetic field strength in tesla (T). A transfer from the lower to the higher state can occur at the resonant frequency (ν), where $\nu = \omega/2\pi$ and ω is the precession frequency of the magnetic moment, μ_s . Therefore, the resonant condition is

$$\nu h = g\mu_B H \quad [4]$$

where h is the Planck constant ($6.626176 \times 10^{-34} \text{ J s}^{-1}$). Hence, applying the resonant signal frequency ν will result in ‘flipping’ the electrons from the lower to the higher state. The amount of microwave energy absorbed is directly proportional to the number of paramagnetic centers, and therefore, in principle, the age of the sample.

After microwave absorption, the two electron populations should be equalized, and no further absorption observed. As can be seen from [Figure 4](#), the resonance condition can be observed either by varying the microwave frequency or the magnetic field intensity. However, because the physical dimensions of the waveguide and the microwave cavity are critically dependent on the microwave frequency, the magnetic field is varied linearly for the ESR measurement. To optimize the signal-to-noise ratio, ESR signals are recorded as derivatives using field modulation ([Figures 2](#) and [4\(a\)](#)). Note that ESR measurements do not require absolute determination of the number of paramagnetic centers; only the relative concentrations (through the ESR response) are needed to establish a dose–response curve. Most modern ESR spectrometers are very stable and do not require internal or external standardization.

Determination of the Dose Rate

The overall dose rate is calculated from the concentrations of the radioactive elements in the sample and their surroundings; only the U and Th decay chains and ^{40}K are of relevance, although there is a minor contribution from ^{87}Rb in sediments, plus a small component from cosmic radiation. There are three types of ionizing radiation from these sources:

- Gamma (γ) rays (photons), with a range in sediments of ~ 30 cm.
- Beta (β) rays (electrons), with a range of ~ 2 mm.
- Alpha (α) rays (He nuclei), with a range of $20\text{--}40$ μm . Alpha particles are less efficient in producing ESR intensity than β and γ radiation. An α -particle efficiency needs to be determined ([Aitken, 1985](#)). The α -efficiency is expressed as a fraction of the equivalent dose for β and γ required to produce the same ESR intensity. This is ~ 0.06 for coral and 0.13 for tooth enamel.

For conversion of the elemental concentrations into dose rates see [Aitken \(1985\)](#), and [Adamiec and Aitken \(1998\)](#). The concentrations within samples are usually very different from those from their surroundings, meaning that the internal and external dose rates need separate evaluation.

External Dose Rate

The calculation of the external dose rate depends on the size of the samples ([Figure 5](#)). It is possible to remove the outer ~ 50 μm of the sample to eliminate the effects of external α -radiation. If it is possible to remove 2 mm, then the β -radiation effects can also be eliminated, leaving only the γ - and cosmic-ray effects. If the grain size of the sample is < 2 mm, obviously it will have β -radiation effects. It is also important to separately calculate the dose for β and γ , since they originate from different volumes of the surrounding sediment, to a distance of 2 mm or 30 cm, respectively ([Figure 5](#)). The external β dose rate can be estimated from the composition

Figure 4 (a) ESR spectrometer. It consists of three main units: a strong electromagnet, a microwave generator, and an electronic processing unit. The sample is measured in the cavity, which is located in a strong magnetic field. The magnetic field can be linearly changed. In resonance, microwave energy is absorbed by the sample, giving rise to an ESR spectrum as shown in Figure 2. (b) Orientation of the magnetic moment of an electron in an external magnetic field. M_s , spin quantum number; μ_s , magnetic moment of spin; ω , precession frequency; ν , microwave frequency that is required for inducing a flip of the magnetic moment into the opposite direction.

of U, Th, and K in the surrounding sediment. In general, the γ dose must be determined using *in situ* measurements using a portable, calibrated γ spectrometer or TL dosimeters. *In situ* measurements have the advantage of reflecting the current-day water content of the sediment, since the presence of water affects the flux of β and γ radiation. It is also important to estimate the cosmic-ray dose rate, which is $\sim 300 \mu\text{Gy year}^{-1}$ at sea level but also is present at a reduced level below ground and varies with altitude as well as latitude.

Internal Dose Rate

The internal dose rate is mainly generated by α and β rays emitted from elements in the sample itself. In secondary carbonates and the constituents of teeth (enamel and

dentine), the U-decay chains are in disequilibrium. This affects the calculated dose, which needs to be calculated mathematically from the observed disequilibrium of ^{238}U . Generally, the α -efficiency is difficult to estimate because of the size requirements, but the best estimates are 0.13 ± 0.02 , 0.07 ± 0.01 , and 0.06 ± 0.02 for tooth enamel, mollusks, and coral, respectively. Dose-rate calculations can become complex if U-series disequilibrium or attenuation needs to be considered (Grün, 1989).

In tooth enamel and mollusks, dose-rate calculations can be further complicated by the accumulation of U in these materials over time. Modern samples are virtually free of U (1–10 ppb), whereas fossil samples may contain up to several hundred ppm U in bones and teeth. The history of the uranium uptake with time may have significant implications for the

Figure 5 Schematic representation of the different external components of natural radiation relevant for dose-rate calculations (Qz, quartz; Fsp, feldspar). Cosmic rays are high-energy particles and are attenuated once they penetrate the sedimentary layers. For practical purposes, the cosmic-ray dose rate becomes negligible at a depth of approximately 20 m. Gamma rays have an average range of 30 cm. In homogeneous, fine-grained sediments, the gamma dose rate can be calculated from the chemical analysis of the bulk sediment. However, if the sediment contains boulders or intercalation of layers with different radioactivity (represented by the two sediment types), the gamma dose rate should be measured *in situ*. Beta rays have average ranges of a few millimeters. In smaller samples, such as teeth or shells, the volume that has received external beta dosage cannot be removed. For dose-rate calculations, the sediment in the immediate surroundings of the sample is analyzed for radioactive elements. Alpha rays have average ranges of a few tens of micrometers. In addition to the external dose-rate sources, samples receive a portion of the internally generated alpha, beta, and gamma rays. Adapted version of Figure 2.2 (p. 42) originally drawn by Steven Stokes from 'An Introduction to Optical Dating' by Aitken (1988), by permission of Oxford University Press.

average dose-rate calculation. Conventionally, two different U-uptake models have been considered: early U uptake (EU) and linear U uptake (LU). For the EU model, it is assumed that all the U present in the teeth today was accumulated shortly after burial, while the LU model assumes the U has been accumulated continuously in a linear fashion. The differences in these calculations are small if the U concentration is moderate. However, with increasing U concentration, the differences between the LU and EU age can be a factor of two. In general interpretations of ESR results, the correct age is considered to be bracketed by the LU and EU results. It has to be recognized that the U-uptake history might be outside the two limiting approaches of LU and EU for 10–20% of teeth samples. Examples of differences are U leaching or strongly delayed U uptake due to hydrologic changes. It should be emphasized that if teeth or shells contain considerable amounts of U, then the standard models may yield grossly discrepant results. There is no *a priori* way to prefer one model over the other.

To overcome the question of unknown U-uptake history, Grün et al. (1988) and Grün (2009) suggested analyzing U-series isotopes in the ESR samples. A one-parameter U-uptake model equation is used:

$$U(t) = U_m(t/T)^{p+1} \quad [5]$$

where $U(t)$ is the uranium concentration at time t , U_m is the measured present-day U concentration, T is the age of the sample (this must be estimated from the U-series result!), and p is an uptake parameter. Some examples of the resulting functions are shown in Figure 6(a). The measurement of U-series isotopic data is used to establish the relationship between apparent U-series age and p -value, starting from a closed system, which corresponds to $p = -1$ (Figure 6(b)). Different constituents of teeth tend to give somewhat different U-series isotopic results, indicating variations in their closed system behavior. The p versus age relationship can then be used, along with other dose information, to compute the dose values for any given age (Figure 6(c)). The projection of measured D_e onto this function gives a combined U-series/ESR age, and returning this calculated age allows one to estimate the corresponding p -values.

Measurement of Radioactive Elements and Isotopes

A large number of analytical techniques are available for estimating the concentrations of radioactive elements. In this field, external γ dose can be measured with TL dosimeters or a γ spectrometer. Other methods for elemental analysis include X-ray fluorescence, inductively coupled plasma mass spectrometry (ICPMS), and neutron activation analysis. In teeth and mollusk shells with U concentrations >0.5 ppm, uranium and thorium concentrations, as well as U-series isotopes, can be measured *in situ* by laser-ablation multicollector ICPMS (Eggins et al., 2005).

Errors

Although error calculations ought to be straightforward (Aitken, 1985, Appendix B), most publications mix random and systematic errors. Most ESR results are quoted to one standard deviation (1σ). The error in D_e is usually within 1–5%. However,

depending on the number of dose parameters and the analytical techniques used, typical precision can be in the range 3–7%. Sources of systematic error derive from calibration of radiation sources of field γ -ray spectrometers. Other systematic errors can arise because of assumptions, particularly if certain parameters cannot be directly measured. The water content of sediments may have changed over time, or some sediments might have had disequilibrium in the U-series system. Additionally, the α -efficiency is difficult to measure and based on a few analyses. These systematic effects can be evaluated only by comparison of ESR results with those of independent dating techniques.

Many archaeological and paleoanthropological sites have been excavated in the past, so determination of external dose rate is not possible. Sometimes, reconstructions have been attempted from museum sediment samples. Clearly, these estimates can have large errors ($>20\%$) since there are many effects that can arise: the samples may be inhomogeneous in U, Th, and K; the physical characteristics of the original sedimentary environment are not preserved; nor is the water content. If teeth contain significant U, errors can be as much as 50% because of the unknown uptake history of U. In the optimal situation where all parameters are known, 1σ errors for teeth and mollusk shells are about 3–9%, and those of corals are lower at 1–3%. Systematic errors in these contexts may be as high as 5%.

Applications of ESR Dating

ESR dating has been applied to a wide variety of materials. Unfortunately, results have sometimes turned out to be questionable, or other dating methods could be applied to a particular material more easily. For example, although it is possible to use ESR for speleothem dating, U-series is much more precise and requires less sample and effort. Particularly because of advances in ICPMS measurements of U-series isotopes, U-series dating of secondary carbonates is now much faster and cheaper than ESR. Some examples of exotic materials where ESR was used to estimate ages are by Okumura et al. (2010), who tried to use ESR to date barites from hydrothermal vent chimneys in the ocean – the ages resulting were considerably different from $^{210}\text{Pb}/^{226}\text{Ra}$ ages. Another example is by Wildberger et al. (2010), who unsuccessfully tried to use ESR in a speleothem study, compared to conventional U–Th approaches. The most successful applications of ESR have been to tooth-enamel dating.

Corals

ESR has played an important role in sorting out the chronology of raised coral reef tracts in Barbados (Schellmann and Radtke, 2004). Figure 7 shows a comparison of ESR age estimates with calibrated radiocarbon and thermal ionization mass spectrometry U-series dates. The ESR age estimates agree well with the ^{14}C results in the range of 0–3500 years, and both methods result in similar errors (Figure 7(a)). When comparing the ESR to U-series results in the range of 70–130 ka, ESR appears to give results somewhat younger than U-series, and errors are significantly larger. This may be due to an overestimate of the U-series age, as ESR is significantly less affected by diagenetic process than U-series (Eggins et al., 2005). Blackwell et al.

Figure 6 Combination of U-series and ESR dating. (a) The U-uptake history using eqn [5] for different p -values. A p -value of -1 corresponds to a closed system (= EU model), $p = 0$ to the linear-uptake model, and $p > 0$ to sublinear, initially delayed U uptake. (b) Apparent U-series ages are calculated from the measured isotopic ratios (i.e., $^{230}\text{Th}/^{234}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$) and a p -value starting from $p = -1$. The crosses indicate the p -values for dentine and enamel that are obtained after the calculation of the U-series/ESR age (c). (c) Using the relationship between p -values and apparent U-series age estimates (from (b)) in combination with all other dose-rate parameters, doses are calculated for any given age. The projection of the measured D_e value onto this function yields the age of the sample, and the p -values for the different constituencies of the tooth can be read from (b). Reproduced from Grün R, Schwarcz HP, and Chadam JM (1988) ESR dating of tooth enamel: Coupled correction for U-uptake and U-series disequilibrium. *Nuclear Tracks and Radiation Measurements* 14: 237–241.

(2007) were able to compare ESR and U-series dates on corals from 6.4 to about 137 ka in age, although the ESR dates of the oldest corals deviated from the U–Th ages to the younger age, as already noted by Eggin et al. (2005).

Mollusk Shells

Mollusk shells are notoriously difficult to date since they tend to accumulate U and exchange CO_2 , causing problems both in

U-series and radiocarbon dating. ESR is also complicated by the fact that dose–response curves are complex, with inflection points, and cannot be easily described by a simple dose-rate function. Based on a large number of samples of known age, a ‘dose-plateau’ procedure was developed and applied to a number of Patagonian shoreline deposits (Figure 8; Schellmann and Radtke, 2003). For deposits correlated with marine isotope stages (MIS) 1–7, it appears possible to use ESR for general assignment of samples to one particular stage. For

Figure 7 Comparison of ESR age estimates on corals with independent age estimates on the same samples. (a) ESR versus calibrated radiocarbon dates. The error bars of both methods are comparable; ESR seems generally to produce slightly older ages. (b) ESR versus U-series ages (screened for initial $^{234}\text{U}/^{238}\text{U}$ ratios close to seawater) on samples from Barbados. The ages of the different units are indicated by arrows (their extension to the 1:1 line). Generally, ESR has significantly larger errors than U-series and seems to slightly underestimate the expected ages, whereas U-series has a tendency to give slightly older age estimates. Adapted from Schellmann G and Radtke U (2004) The marine Quaternary of Barbados. *Kölner Geographische Arbeiten* 81: 1–137, with permission.

Figure 8 Comparison of ESR age estimates on mollusk shells from marine deposits (indicated by the Pa numbers) in Patagonia with independent geomorphological assessments. ESR can be used for the secure assignment of the remnants of sea-level high stands to marine isotope stages (MIS) 1, 5, and 7. However, the uncertainties in the ESR age estimates of older deposits do not allow correlations of geological formations to a specific MIS. Adapted from Schellmann G and Radtke U (2003) Die Datierung litoraler Ablagerungen (Korallenriffe, Stranwälle, Küstendünen) mit Hilfe der Elektronenspin-Resonanz-Methode (ESR). *Essener Geographische Arbeiten* 35: 95–113, with permission.

Figure 9 The age of BC5 in context with the ESR and ^{14}C chronology for Border Cave. Lowercase letters following the sample number denote subsamples of a single tooth, and uppercase letters denote separate enamel fragments. The two bracketed results were not used for the calculation of the average ages of the units. Adapted from Grün R, Beaumont P, Tobias PV, and Eggins S (2003) On the age of Border Cave 5 human mandible. *Journal of Human Evolution* 45: 155–167; Bird MI, Fifield LK, Santos GM, et al. (2003) Radiocarbon dating from 40–0 ka BP at Border Cave, South Africa. *Quaternary Science Reviews* 22: 943–947.

older units, errors become too large. However, ESR was very important in eradicating the myth of an MIS-3 sea-level high stand in South America, which was due entirely to radiocarbon dating of samples without proper cleaning to remove CO₂ contamination (Radtko, 1989). Titschack et al. (2009) were able to combine ESR with microstructure and stable-isotope studies of shells to suggest that ESR could be used to indicate times of diagenesis from aragonite to calcite in shells from Rhodes (Greece).

Tooth Enamel

ESR dating of tooth enamel has been applied in a number of archaeological and paleoanthropological sites (Grün, 1997, 2000; Grün and Stringer, 1991; Rink, 1997). For early modern human sites in the Klasies River Mouth Cave (South Africa), as well as Qafzeh and Skhul in Israel, ESR dating has demonstrated the occurrence of anatomically modern humans approximately 100 000 years ago.

Recently, Falguères et al. (2010) were able to demonstrate the usefulness of combined ESR and U-series methods to date several major Acheulian sites in Spain, Italy, and France to the period of 300–600 ka. Another interesting example is the study of Skinner et al. (2007b), who used ESR coupled with ²³⁰Th/²³⁴U to develop an LU model to establish a date of 57–87 ka on teeth from a Paleolithic site, Obi-Rakhmat, in Uzbekistan. ¹⁴C ages at this site suggest a later age, although this dating is still part of an ongoing discussion. Krivoshapkin et al. (2010) noted that different uptake models in Skinner et al. (2007b) give different results and argue for a lower age close to the limit of ¹⁴C dating. Liberda et al. (2010) have been able to use ESR in tooth enamel of the Mousterian layer (#20) from El Castillo, Spain, to obtain ages of 42.7 ± 6.4 ka, consistent with ¹⁴C dates on the same horizons. Yin et al. (2011) applied combined ESR and U-series to dating of the controversial Dali skull. U-series and ESR gave consistent results for one tooth, of about 281 ± 46 ka, although measurements on other teeth gave discrepancies between U-series and ESR dates.

The important strength of ESR is that it is virtually nondestructive and allows direct analysis of tooth-enamel fragments from human fossils. The archaeological and paleoanthropological site of Border Cave contains one of the best examples of a detailed ESR dating sequence (Figure 9). The dating results for the younger horizons agree well with radiocarbon ages on charcoal collected from the same layers. Of particular interest is the age of Border Cave 5, one of the few early anatomically modern hominid fossils found *in situ* at this location. A study based on the analysis of nitrogen contents and infrared splitting factors indicated that BC5 could be as young as the Iron Age (~1000 years old at this site; Sillen and Morris, 1996). ESR analysis of tooth fragments and determination of the U concentration by ICPMS agreed with the age of the older samples in the surrounding for this level (Figure 9). The best age estimate of 74 ± 5 ka implies that fully modern humans lived in southern Africa significantly earlier than in Europe.

In some types of samples, the ESR signal can be very durable; Skinner et al. (2007a) discuss the dating of crocodile teeth from Australia with ages of >1 My.

Bones

All attempts to obtain reliable ESR dates on bones have been unsuccessful, although this would be a most useful application. Unfortunately, bones absorb more U than teeth, and the mineral phase is only 40–60% of the bone. During fossilization, the mineralogical composition changes, resulting in new minerals and disintegration of others, as well as conversion of an amorphous phase into hydroxyapatite. Formation of new mineral phases with time will result in new electronic defects (traps), resulting in difficulty in estimating age due to these additional variables, no matter which U-uptake model is used.

Quartz

ESR study of quartz has been used for dating of river terraces (Voinchet et al., 2004). The main advantage of ESR over luminescence is that the Al and Ti centers in quartz give significantly higher ESR saturation levels than luminescence methods.

This means older samples should be routinely datable. The disadvantage of ESR is the very long bleaching times required to reset these paramagnetic centers (several hours for Ti and days for Al). This makes it difficult to know whether samples were completely bleached before burial. Comprehensive comparisons of ESR versus TL and OSL for quartz are still needed. In a pilot study, ESR was used to reconstruct the thermal history of the Eldzhurtinskiy granite, in the Caucasus region (Grün et al., 1999). The implication of this study was that ESR has a possible application in detailed landscape reconstruction in rapidly uplifting terrains. More recently, Tissoux et al. (2008) have attempted to apply ESR to quartz in fluvial deposits, who also undertook bleaching experiments on the Ti and Al centers. Similarly, Voinchet et al. (2007) looked at fluvial sediments in order to try to establish the optimal Al bleaching time, showing that the samples can be bleached in the first kilometer of transport, even though laboratory experiments suggest longer bleaching times.

Introduction

Oribatid mite studies are only now reaching the main stream of Quaternary investigation as researchers seek additional methods for recognizing climate change based on organismal proxies of habitat. In most aquatic and semiaquatic environments, these minute arthropods ([Figure 1](#)) are preserved well enough and in sufficient numbers to make them very useful for serious investigations of paleoclimate, paleoecology, stratigraphy, or paleolimnology. But they have been largely disregarded, perhaps because their study requires a patient fossil picker and a skilled microscopist with systematic knowledge of the group. Because rewards of information are potentially large, this situation has begun to change. At this point in the development of Paleoacarology, workers are trying to learn enough about the quality and subtlety of the oribatid fossil record to be able to trust interpretations of

that record without a need for secondary corroboration. Errors will be made on the way, and this is a time for conservative interpretation, but it appears that the oribatid fossil record is very robust and full of subtlety and will emerge from careful efforts by knowledgeable paleoacarologists.

Mites in postglacial sediments are often alluded to as being 'subfossil.' When an organism dies, or when it molts, the remains fall to the substrate. When they are interred in a natural manner, they become fossils. A vast array of postdepositional circumstances may befall these fossils; on rare occasions they will even be replaced by mineral matter, but more likely they will not, nor is replacement of any sort of validation required for them to be 'fossil.' Most will be lost to processes of decay and/or biogeochemistry. To be fossil, they need only survive these threats long enough to fall under the inspection of the curious scientist. Often the term 'subfossil' is employed as an

Figure 1 *Hydrozetes* sp. seen in dorsal oblique view illustrating the dorsal shield (N, notogaster) and prodorsal shield (P), the lenticulus (L), and the right sensory sensillus (S) at tip of arrow. Fossil *Hydrozetes* sp. often preserve proximal leg segments but distal segments seen on this recent specimen are usually absent on fossils. Modified from Erickson JM (1988) Fossil oribatid mites as tools for Quaternary paleoecologists: Preservation quality, quantities, and taphonomy. In: Laub RS, Miller NG, and Steadman DW (eds.) *late Pleistocene and early Holocene Paleocology and Archaeology of the Eastern Great Lakes Region*. *Bulletin of the Buffalo Society of Natural Sciences*, vol. 33, pp. 207–226. Buffalo, NY: Buffalo Society of Natural Sciences.

apology for expressing the geologic age of the specimen when none is needed. There is no gradation from cadaver to skeleton to fossilwannabe to subfossil to perifossil to fossil such as the term subfossil implies. We consider this term inappropriate and recommend it not be used. As soon as an organism is deposited as part of the sediment it is a fossil and workers must begin to think about it in terms of geologic processes and their implications. In particular, one of us (JME) believes that by considering late Pleistocene and Holocene mites, and most other geologically young fossils, as ‘subfossils’ they have not been properly treated by either neontologists or paleontologists.

The presence of fossil oribatids was recognized a century ago by Nordenskiöld (1901), and their potential was recognized by Frey (1964) who suggested that fossil mites would one day prove useful to Quaternary geoscientists in much the same ways that fossil pollen and diatoms were then proving to be. Coleoptera, Cladocera, and Chironomida were beginning to be recognized in the Quaternary fossil record (Coope, 1967; Frey, 1964) as the concept of paleoclimate and paleohabitat proxies emerged. Each of these taxa has its own distinctive information to provide to Quaternary paleoecologists. Our purpose here will be to clarify current, distinctive uses of fossil Oribatida. It will include an introduction to the two eras of fossil mite study, the descriptive era and the applied era, as these can be useful ways to approach the information now available to paleoacarologists. First, a brief introduction to the biological affinities and habits of the group is in order.

What are Oribatid Mites?

The arthropod subclass Acari represents an enormous diversity of minute, eight-legged animals identified as mites and ticks. Reduced segmentation and lack of an independent head structure readily differentiate them from arachnid relatives such as spiders and scorpions (Walter and Proctor, 1999). These globally distributed and ancient animals utilize a wide variety of trophic styles, while behaviorally interacting with other organisms and natural systems to fill countless niches. Oribatid mites, commonly referred to as ‘moss mites’ or ‘beetle mites,’ are a diverse group of mostly terrestrial acarids with densities reaching hundreds of thousands per square meter in rich organic soil horizons, particularly those that have well-developed fermentation layers (Norton, 1990). They are the dominant arthropod in temperate to subtropical forest habitats. In addition, they are well distributed in or on other substrates, including decaying woody and nonwoody vascular plants, macro fungi, mosses, algae, lichens and even forest canopies (Behan-Pelletier, 2000; Behan-Pelletier and Bissett, 1994; Norton, 1985). Figure 2 presents an array of extant oribatids derived primarily from semiaquatic and aquatic habitats. These are species that are commonly fossilized. Their small size, usually between 200 and 800 μm, allows them to dwell in the microclimate boundary layer of the aforementioned vegetation types.

These minute chelicerates play a significant role in decomposition and nutrient cycling processes as saprophagous and mycophagous organisms grazing on organic residues and microflora by means of direct (selective feeding) and indirect (comminution of particles) relationships with microflora. The average generation time from egg to adult is approximately 1–3 years in temperate climates, and up to 7 years in cold climates (Cannon and Block, 1988; Norton, 1990). Rather than being adaptive, long generation times and relatively low fecundity have been explained as constraints of low secondary production, associated with relatively low quality food compared to that of other arachnids (Norton, 1994). In addition to high densities, more than 10 000 described species in over 1100 genera representing approximately 173 families create a diverse fauna that frequently exceeds 80% of all microarthropods in the soil (Walter and Proctor, 1999). Only a small set of oribatid taxa, 15 genera in 11 families, is hydrophilic, or affiliated with aquatic and semiaquatic habitats (Behan-Pelletier and Eamer, 2007). They are widely distributed in freshwater habitats, but their species diversity is low compared to that of terrestrial communities, and little is known about the microhabitat requirements of particular species. Although most oribatid mites reproduce sexually, approximately 10% are obligatorily parthenogenic, and this mode is dominant in aquatic habitats (Norton and Palmer, 1991; Norton et al., 1993). Fossil *Hydrozetes* spp. are occasionally preserved with unborn juveniles in the body cavity.

Hydrophilic oribatids exhibit multiple morphological and physiological adaptations to the aquatic medium. Brachypylina are active, and have well-developed tracheal systems, usually aided by a ‘plastron’ for gas exchange. Another adaptation is controlled floatation or ‘levitation’ that entails the unexplained formation of an air bubble in the gut, best known in the genus *Hydrozetes* (Newell, 1945). Though not unique to hydrophilic oribatids, a primitive light receptor (lenticulus;

Figure 2 Recent, adult oribatid mites such as may be found in and around aquatic and semiaquatic habitats in northeastern North America. Figure 1) is well developed in *Hydrozetes* and *Tegeocranellus* (**Figures 2(12), 2(13), 2(21), 2(22)**). No oribatids are known to swim, and few show any leg modifications. One exception is *Mucronothrus nasalis*, which has exceptionally flexible legs and is particularly tenacious in moving currents (**Norton et al., 1988**).

How are Oribatids Fossilized?

Widespread distribution and large population numbers of the Oribatida make them excellent candidates for fossilization in deposits near their normal dwelling site. Most fossil mites belong to the Brachypylina because of the chitinous sclerotization and fused skeleton of the group. Ptychotine oribatids have skeletons sclerotized with calcium oxalate (**Norton and Behan-**

Pelletier, 1991) which seem readily destroyed geochemically after death. **Erickson et al. (1985)** and **Erickson (1986, 1988)** have noted the advantages mites offer the Quaternary scientist who seeks local paleoenvironmental information about a site. They do not fly, nor do they suffer much overland or stream transport before they disarticulate, so where found, they are demonstrably close to their life habitat. Hydrophilic taxa likely matured within the basin of deposition; they were autochthonous, whereas specimens arriving at the site of deposition from surrounding terrain are considered allogenic or allochthonous (**Drouk, 1997; Erickson, 1988**). Mites enter the fossil record by overland precipitation runoff, local stream inflow, swash zone wave action, in-fall of vegetation, air-fall from overhanging vegetation and local wind transport of sediment (**Figure 3**). Because they do not fly as beetles do, nor blow long distances

Figure 3 Cartoon demonstrating that oribatid mites reach the depositional environment by several means representative of their original microhabitat domiciles. Tree resins preserved oribatids in amber, a source for most pre-Quaternary oribatid specimens. Mites enter lakes and marshes by overland runoff and shoreline erosion, by dropping from overhanging vegetation, and by *in situ* death of aquatic taxa. Sediment-focusing processes may transport them toward the center of the basin.

on the wind as many pollen species do, they offer excellent characteristics as proxies of local habitat and climate, particularly when those are a reflection of moisture conditions. Because of this they are beginning to emerge as an important tool for Quaternary studies.

Development of Quaternary Oribatid Studies

Human knowledge of organisms is organized and framed around the identity of the creature being studied. That identification is the link between past and future studies making essential the ability to identify the subject of study. The description of oribatid genera and species has been essential to the science, and knowledge of its literature among key workers is a necessity for the use of mites in Quaternary studies.

The Descriptive Era

Quaternary mite neontological studies are based upon the work of acarologists who pioneered the field and devoted great effort toward discovering and describing new taxa. Much of the early work beginning around the beginning of the twentieth century was done by European and North American acarologists that included researchers such as Berlese, Michael, Banks, and Ewing and the expansive morphological works of Grandjean. The next wave of acarologists who sought to better know the global fauna included such workers as Hammer, J. Balogh, Mahunka, Aoki, Jacot, and Woolley. The two-volume work by Balogh and Balogh (1992) summarized the genera of the world in a most useful synthesis. Many more acarologists have contributed significantly to the field but our aim here is to provide entry to the literature of the group.

As much of the pioneer literature was being compiled, Strenzke, Knülle, Willmann, Karpinnen, and Sellnick explored

wider directions of physiology and ecology. Strenzke and Knülle were both interested in community structure and habitat partitioning that influenced present paleontological studies. Sellnick pioneered studies of fossil mites in amber. Amber has been the source of most geologically old fossil material bearing on the evolution of the Oribatida with new taxa continuing to be recognized (Arillo et al., 2008).

Contemporary experts who have made major contributions to oribatid study include Kethley, Walter, Reeves, Alberti, Marshall, and Bocard. Two North American acarologists who have greatly influenced Quaternary fossil mite applications are R. A. Norton and V. Behan-Pelletier. Norton has contributed to comparative morphology, systematics, and paleontology, as well as evolutionary aspects of mite reproductive biology, and ecological roles in decomposer food webs. Behan-Pelletier's expertise includes systematics, biogeography, and ecology of boreal brachypylina mites, especially members of the Ceratozetoidea and aquatic and peatland taxa. All of the aforementioned acarologists' names are intended to be valuable to researchers as keywords to the primary literature. Lastly, the bibliography of oribatid papers of the world compiled by Schatz (2004) and the emerging PDF database being compiled by Norton and Behan-Pelletier are invaluable reference tools.

The Applications Era

Applications for study of oribatid mites have been clear in the agricultural disciplines for a half century or more, but their study in the fossil record remained largely systematic or a cataloging of species occurrences until the rise of interest in climate-related Quaternary research became part of the basic research of Geology after the second half of the twentieth century. At that point, the ecological approaches to oribatid study by Strenzke (1952) and Knülle (1957) made clear their potential utility as proxies of microhabitat and, by extension, as indices of the paleoclimate. It remained only to raise awareness of researchers to those possibilities.

Two areas of application began to emerge. In Europe, Denford (1978) discussed the possible information that oribatid and mesostigmatid mites and related taxa, such as ticks and lice that accompany humans and occupy their dwelling sites, should be able to provide to archaeologists. Generally brachypylina oribatids are far better represented as fossils than their predatory mesostigmatid relatives which have more unsclerotized connective tissue between body segments as we discuss below.

After Denford (1978) called attention to their potential use in archaeology, European acarologists initiated a group of studies aimed at clarification of habitat conditions during human occupation of various archaeological sites, particularly in lowland mires where peat accumulation preserved oribatids (Schelvis, 1987, 1989, 1990). In 1989, Schelvis and Van Geel demonstrated that the record of fossil mite occurrences and abundances through a 2000-year-long section at Usselo, Netherlands, reflected changes similar to those of paleobotanical data from the same section. Schelvis' (1990) study improved on the use of fossil oribatids by integrating the concept of modern habitat groups, 'synusiae' of Strenzke (1952), and the seventeen 'isovalent' mite occurrence groups

of Knülle (1957), predicated on soil moisture, into a semi-quantitative framework based on numbers of recovered individuals of each species. Occurrence values based on counts of each mite species as indexed to its assigned group, ratioed to totals for each group, then provide the basis for calculation of percentages of occurrence of each group among the entire fauna. The resulting spectra of ecological groups, plotted as pie diagrams, formed the basis for making strong inferences of habitat types that prevailed in the past at particular archaeological sites. Schelvis' (1990, 1998) method potentially has great power, especially if it is employed through closely-sampled sections of otherwise homogeneous-appearing sediments, but it has not been exploited yet to full advantage by the archaeological community. In Europe, synusia and isovalent groups of mites are available as tools at the species level whereas these are yet to be established elsewhere.

A group of acarologists in Scandinavia and Russia combined a tradition of systematic and community structure study of modern bog and mire faunas with analysis of the historical development of those faunas based on fossils. These works are more numerous than can be cited here, but some workers who have been deeply involved include Karppinen, Koponen, Markkula, Krivolutsky, and Drouk. Drouk (1997) has pointed out both the applications and the pitfalls of acarological analysis that have emerged from these efforts by suggesting that present knowledge of oribatid distributions and their controlling factors are not yet well enough known, and further, it appears that preglacial mite community species compositions have not been precisely duplicated when glacial conditions have left an area thus making analysis by analogy less trustworthy. Nevertheless, analyses of species distribution, by habitat-

related assemblage structure and by following changes in composition of an ecological group (e.g., Schelvis, 1990) through succession have all been applied satisfactorily. Presently, oribatid community structure in carefully analyzed habitats (e.g., de la Riva-Caballero et al., 2010) is providing ranges of temperature, moisture content, pH and trophic conditions. Thus, oribatid species have demonstrated their utility as contributors to multiproxy reconstructions, having greater precision than that afforded by single proxy studies (Larsen et al., 2006). This is one future for oribatid applications.

In North America, beginnings of the application process focused on understanding relationships of fossil mites to sediments typically available from Quaternary sites. Waters (1979) examined fossil content of several lithologies of late Pleistocene and Holocene sediments cored from Glovers Pond, a 20 000-year-old spring-fed lake in New Jersey, USA. Clastics, including sand, silt and clay, were devoid of oribatids, but biogenic sediments from both littoral and profundal settings, including peat, marl and gyttja contain fossil oribatids in quantities large enough to allow quantitative comparative analyses that are replicable even at small sample sizes available from 5- or 6-cm-diameter cores. Waters' work established that sample sizes as small as 10 g (dry weight) of marl or gyttja contained enough fossil mites to allow comparisons within cores and between cores in the same lake basin. Erickson et al. (1985) noted that 1 g dry weight of lake sediment contained an average of 11 mites thus suggesting that samples >5–7 g wet samples could give internally consistent comparisons of mite populations within cores when data are standardized to 10 g dry weight. A single 30 g, wet-weight sample produced 620 fossil mites. Metzger (1985) conducted up-core

Figure 4 Suggested protocol for lab procedures useful when retrieving, separating, and identifying fossil oribatid mites. Modified from Erickson JM (1988) Fossil oribatid mites as tools for Quaternary paleoecologists: Preservation quality, quantities, and taphonomy. In: Laub RS, Miller NG, and Steadman DW (eds.) *late Pleistocene and early Holocene Paleoecology and Archaeology of the Eastern Great Lakes Region*. *Bulletin of the Buffalo Society of Natural Sciences*, vol. 33, pp. 207–226. Buffalo, NY: Buffalo Society of Natural Sciences.

analysis of mite faunas at Glovers Pond by determining numbers of aquatic, semiaquatic and terrestrial taxa as percentages of mite populations in each equalized, 10-g sample through 3 m of core. Erickson (1987, 1988) pointed out that changes in percentage of aquatic mites up-core document changes in lake level within the basin over time preparing the foundation for biostratigraphic studies. In 1997, Erickson suggested that oribatid mite studies should be applied to questions of global climate change. Since that time, reports based on interesting applications of oribatid data have appeared with some regularity. Thus the taphonomic or preservational aspects as well as habitat preferences of oribatids have been emphasized in much of this work. These will provide focus for the discussions that follows.

Techniques and Methods

Obviously, during micropaleontological studies the value of the final product is controlled dramatically by the care and planning of the initial sampling. Sampling techniques for live oribatids include those employed by soil scientists who investigate soil faunas of all types. Soil or vegetative litter samples are placed on a screen in Tullgren or Berlese funnels and then under light (Krantz, 1978) which desiccates the mineral and organic matrix prompting soil organisms to move downward under positive geotaxis until they drop through a screen into the funnel for capture. Fossil mites are more challenging to sample and a variety of techniques may be employed to extract and study them (Krivolutsky and Druk, 1986; Krivolutsky et al., 1990).

Sediment Sampling for Oribatid Mites

Field sampling techniques as would be used for many Quaternary micropaleontological studies such as pollen, mollusks, or Coleoptera are applicable to oribatid sampling, but it should be pointed out that archaeological sampling and geological sampling requirements are often distinctly different (Coetzee and Brink, 2003; Erickson, 1988; Schelvis, 1997, 1998; Solhøy, 2001). Slot and trench samples of exposed soil or quarry faces are readily obtained using clean, durable, self-sealing plastic bags which are easily labeled. Of primary import is that stratigraphic interval and sample integrity are maintained from the outset. We wish to reinforce the notion that oribatid mites, like pollen, are ubiquitous in the modern environment. Samples that may be set aside in the field, or even in the lab, although monitored for contamination by physical factors, may yet be contaminated by mobile oribatids unless they are sealed immediately (Drouk, 1997). If one encounters an oribatid that still possesses complete tibial and tarsal leg segmentation, it should be regarded with suspicion during faunal analysis because fossil mites rarely retain distal leg appendages. Field samples and cores may be refrigerated to prevent molding, and desiccation should be prevented at all times. Sample sizes ranging from 10 to 1000 g can produce useful data depending on the objectives of the study.

Cored sediments present more rigid sampling situations in which core diameter controls sample availability and sample thickness determine the amount of sediment for use by the

paleoacarologist. Most cores are intended for multiple types of analysis. Sampling protocols (Figure 4) that extract organic matter by wet-sieving may permit physical and chemical studies of sediments passed through the sieves if distilled water is the washing agent. Oribatids, and most entomological remains, are best preserved in ethanol (70% or greater) and sediment samples may be immediately disbursed in this when gathered if other analyses are not needed. One half of a 1 cm-thick slice through a 4-cm-diameter core will provide sufficient numbers of oribatid mites for studies of lake level and climate change in gyttja, marl or peat substrates.

A cautionary note is appropriate. Fossil oribatids seem not uniformly distributed throughout some deposits. An unpublished experience of the senior author involves research done with Dr. Paul Karrow on the Don Brickyard Beds of Ontario,

Figure 5 SEM images of typical fossil hydrophilic and aquatic mites from Erickson et al. (2003), illustrating the quality of preservation that is often present in lacustrine-authigenic sediment. 1, *Heterozetes aquaticus* lateral view; 2, anterior view of *Tegeribates* sp.; 3, dorsal view of anterior half of *H. aquaticus*; 4, *Naiazetes reevesi* seen in dorsal view; 5, oblique view of *Hydrozetes* sp. Reproduced from Erickson JM, Platt RB, Jr., and Jennings DH (2003) Holocene fossil oribatid mite biofacies as proxies of paleohabitat at the Hiscock Site, Byron, NY. In: Laub RS (ed.) *Proceedings of the Second Smith Symposium: The Hiscock Site: Late Pleistocene and Holocene Paleoeecology and Archaeology of Western New York State. Bulletin of the Buffalo Society of Natural Sciences*, vol. 37, pp. 176–189. Buffalo, NY: Buffalo Society of Natural Sciences.

Canada, that involved resampling of units which had produced a mite fauna some years earlier. The original work was interrupted and samples lost. Resampling of the same horizons was accomplished several years later by the same researcher who took the original samples. Processing of the resampled sediments by the same techniques produced much insect material but did not yield any oribatids. This lack of reproducibility is surprising because it is counter to a number of other experiences, yet it is appropriate cautionary information to provide herein.

Weight versus volume

Efforts to apply oribatid data to solution of geologic problems require that the data be internally comparable within a study. Hopefully, results will be comparable between studies as well. Cored sediments induce uncertainties that make data semi-quantitative at best, because of both deposition- and compaction-rate inequalities. We suggest that sampling by weight rather than by volume is appropriate for oribatid study. Furthermore, adjusting sample sizes to dry weight equivalents is

the most consistent means of assuring comparability. We have normalized samples to 10 g dry weight in several studies (Erickson, 1997; Pickard, 1993) either by sampling dried sediments (not recommended) or by determining desiccation factors of wet sediment and standardizing by using the wet/dry ratio.

Fossil mite extraction

Disbursed samples may be processed in several ways as suggested in Figure 4. From marl they may be separated by wet-sieving to retain material >0.05 mm after which they may be decanted with very weak HCl (maximum strength three parts per thousand) to remove the calcium carbonate. Alternatively, the samples may be stored in ethanol and carbonates removed from individual mites by immersing specimens of interest in a drop or two of the HCl on a depression slide. From gyttja they may be dispersed and sieved and the organics placed in ethanol. Peat should be mechanically disbursed in alcohol as thoroughly as possible. A shaking device may be used during the disbursal process (Figure 4) but this may further remove leg segments that have remained with the mite, nor are they

Figure 6 Fossil oribatids from the Hiscock Site, Byron, NY. 1, Ventral views (except 1G, I) of fossils from biofacies 1. recommended if taphonomic study (see section 'Taphonomic Analysis') is an objective. Under no circumstances should oribatids be cleaned by sonic cleaning methods because they are brittle and shatter easily with only brief exposure.

Separation of individual mites from the background sample is accomplished by hand-picking under magnification either with or without employing a floatation process (Figure 4). Kerosene (e.g., Coope, 1986; Kenward et al., 1980), heptane

(Walter et al., 1987), drying and rewetting (Drouk, 1997) saturated magnesium sulfate (Salt and Hollick, 1944) or saturated NaCl solution (Fain and Hart, 1986) may each be used to suspend oribatids above dispersed sediment by means of density differences, but each requires a distinct protocol of sample preparation not considered here. We prefer to use the saturated salt (NaCl) solution because it is effective and benign (Coetzee and Brink, 2003; Erickson, 1988). Samples stored in ethanol are spread thinly over the bottom of a petri dish and covered by a thin layer of ethanol. Using a dropper or pipette, introduce saturated salt solution to completely cover the sample. Stir sediment gently with a pick and place on microscope stage. Sediment-filled, alcohol-saturated specimens generally will float somewhat, others will reach the surface of the dense, salt solution. As oribatid fossils float to the surface, they may be removed by fine-tipped dropper to a storage vial of ethanol. We have verified the quality of NaCl separations by hand-picking the postflotation residues of random samples and have found that some few oribatids deeply entwined within

organic debris are not floated although they often reorient in the dish so that the mite is upward and visible for inspection. Final visual inspection of the sample is always advised. The drying-wetting method (Drouk, 1997) often introduces air bubbles into the body cavity that are difficult to remove. Alternatively, fossils may be hand-picked from dispersed sediment by dropper without first floating them. Reminders of salt-treated samples may be washed through a sieve (80 µm) and stored again in ethanol or discarded.

Identification

Utility of mite information is dependant upon the level to which taxa are identified. A phase contrast microscope with 1000× magnification is essential for species-level identification. Fossils may be mounted permanently on glass slides using Hoyers or de Faures medium (Krantz, 1978), cured for 24 h in a warm oven and sealed by ringing with glyptol after which they may be stored.

Table 1 Oribatid mite biofacies based on fossil occurrences in excavation pits G7SW, H5SW (=G5NW), H3SW, and I3NE at the Hiscock Site, Byron, NY. Large samples from the top of the Pleistocene Cobble and Fibrous Gravelly Clay Layers of H3SW yielded no mite fossils. Samples are arranged lithostratigraphically, and taxa are grouped by habitat categories as described in text. Biofacies, shaded horizontally for ease of recognition, suggest the following conditions: Basal zone corresponding to Pleistocene clastic sediments barren of mite fossils; biofacies 1, cool or mild, moist, fluctuating water table (=WT); 2, dry, hot? or cold?, very low WT; 3, mild, very wet, very high WT; 4, similar to present but more moist, with fluctuating WT and vernal pond conditions, becoming drier toward the top where an unsampled biofacies may exist. Position of the discontinuous, early Holocene, Gelatinous Woody Layer is also shaded to highlight its stratigraphic uniqueness

Many oribatid workers prefer to examine specimens using the Grandjean method by suspending them in lactic acid in a depression slide half covered by a moveable cover slip under which the specimen is maneuvered with a fine needle. The mite may be rotated for inspection of all necessary features after which it is returned to the storage vial of ethanol. This method works best for cleared specimens of live material. Fossils are

often not preserved well enough to justify manipulation and the attendant risk of damage in their brittle state. Practicing the technique with recent material is helpful before working with fossils. A thorough discussion of sorting and study techniques can be found in the summary by Solhøy (2001) or in other synoptic works (Drouk, 1997; Schelvis, 1997).

Scanning electron microscopy (SEM) can be an important tool for identification of fossil mites (Figure 5). It is most useful for satisfying questions raised during light microscopy. Sediment-filled specimens and those that are badly deformed may yet be identified using SEM. The only caveat is that SEM requires a permanent mount of the specimen and therefore archiving of the SEM stub along with other voucher materials is necessary.

Identification is aided by keys available at several taxonomic levels. The generic key by Norton (1990) or that by Balogh and Balogh (1992) permit initial identification. Workers should then refer to the extensive oribatid primary literature, summarized by Schatz (2004), containing keys to species. In Canada, many important systematic and ecological studies by Behan-Pelletier are focused on hydrophilic species, such as *Limnozetes*, the Family Zetomimidae (Behan-Pelletier, 1989; Behan-Pelletier and Eamer, 2003) and peatland oribatid faunas.

Sectors of Application

Applications for fossil oribatid mites generally parallel those for other microbiota in geological and archaeological research. The uniqueness of the group as a tool for Quaternary studies emerges from its unique life properties and the unique conditions of preservation which are a response to those life habits. Biostratigraphic, biofacies, faunal assemblage, paleoclimate and taphonomic studies, all of which potentially rest on the importance of initial taxonomic study – the skill being lost with the passing generation – each has import to the Quaternary scientist because when these organisms occur in the fossil record they are: (1) essentially of local derivation (see discussions in Erickson, 1988 and Drouk, 1997); (2) reflective of nearby soil and vegetation conditions; (3) preserved in numbers that often reflect population sizes; (4) preserved in taphonomic conditions that reflect local geologic setting; (5) are locally and regionally distributed according to climate factors of moisture and temperature; and (6) readily recognized after the initial identifications are established. Recent investigations of fossil oribatid mites serve as examples for mite applications to each of these sectors.

Biostratigraphic Applications

Many archaeological studies of oribatid fossils involve analysis of surface samples or of spot samples associated with human or animal fossils or artifacts (Foddai and Minelli, 1994; Schelvis, 1990, 1992, 1997). Studies are now demonstrating that close sampling for oribatids through longer stratigraphic intervals (Bennike, 2000; Erickson, 1987, 1988, 1997; Erickson and Solod, 2002; Luoto, 2009; Solhøy and Solhøy, 2000) can provide an unusual wealth of information of several sorts important to studies of postglacial history and climate change. We discuss some examples of these here.

Figure 12 Numbers of terrestrial oribatid fossils in the study interval at Glovers Pond, NJ. Inset is *Ommatocepheus clavatus*, an inhabitant of lichen grown on rocks and tree bark.

Biozonation by species acme zones

In the study by Schelvis and Van Geel (1989) noted above, the first attempt to finely sample a stratigraphic section and to relate oribatid content to previously understood biostratigraphic parameters such as pollen and macrophyte zonation was made. It demonstrated that oribatid populations through a 2.5 m section of lake and bog sediment spanning roughly 2000 years responded to changing climate, and climate-influenced habitat alteration, in patterns that were very similar to those found in pollen spectra alone. Mite abundance data coincided remarkably well with pollen zone and subzone boundaries. A close examination of occurrence data would suggest that more information is available in this stratigraphic record than the newness of the approach allowed Schelvis and Van Geel to recognize. In their work, populations of the aquatic species *Hydrozetes lacustris* demonstrate two additional biostratigraphic subzones suggestive of those related to climate change in the Preboreal recorded by *Hydrozetes* species elsewhere (Erickson and Solod, 2002, 2007; Solhøy and Solhøy, 2000). In these studies, increases in populations of the aquatic mites reflect increases in water temperature, or depth, and availability of nutrients in the aquatic system. The acme of these populations defines the peak of such conditions in the sediment record. Records of very low, or no, occurrences of *Hydrozetes* spp. suggest cold climates with reduced nutrient cycling in lakes and bogs, or prolonged dry conditions (Erickson, 1987).

It is noteworthy that these same interpretations are recognized independently using different species in a 7000-year record from Signy Island in the Antarctic where two species

of oribatid mite are the largest land organisms on the island (Hodgson and Convey, 2005). *Alaskozetes antarcticus* and *Halozetes belgicae*, basically terrestrial taxa, have partitioned the lowland terrains from the tidal flats to 200 m elevation where they are both found in lake catchments in differing numbers. Hodgson and Convey (2005) report peak occurrences (acmes) of each species in similar positions in Heywood and Sombre Lakes approximately 1600–1700 cal years BP. This important study demonstrates utility of oribatid acme zones as a means of correlation in Quaternary sediments between local basins, but the climate change interpretation is of central interest.

Biofacies analysis

Biofacies analysis by oribatid distributions in five separate 1-m² quadrants exposing a 1.5-m section of peat at the Hiscock Site in New York, USA, was accomplished by taking horizontal slot samples 1.5 cm thick × 10 cm long × 5 cm deep in the wall of excavated quadrants with the goals of defining biostratigraphic zones and testing their relationships to the physical stratigraphy of the site (Erickson et al., 2003). Biofacies were based on the presence and absence of the species seen in Figures 6 and 7. These were next assigned to eight habitat-related assemblages including cosmopolitan, xerophilic/bryophilic, bryophilic, herbaceous, semiaquatic, aquatic, arboricolous, and epigeal groupings loosely based upon preferred habitat information related to the more than 35 species determined. Occurrence data are displayed stratigraphically in Table 1.

Figure 13 Fossil population data for *Limnozetes rugosus*, *Hydrozetes* spp. and terrestrial taxa (undifferentiated) displayed against stratigraphic and lithologic information from Glovers Pond core C-I-4. Data for Glovers Pond core C-I-4 with depth in centimeters after Solod (2001). Reproduced from Erickson JM and Solod AM (2002) Recognition of the Younger Dryas interval by quantitative biozonation of fossil oribatid mites at Glovers Pond, NJ. *XI International Congress of Acarology, Program and Abstract Book*, pp. 175–176; Erickson JM and Solod AM (2007) Recognition of postglacial cold intervals by quantitative biozonation of fossil oribatid mites. In: Morales-Malacara JB, Behan-Pelletier V, Ueckermann E, et al. (eds.) *Acarology XI: Proceedings of the International Congress*, pp. 9–16. Mexico: Instituto de Biología, UNAM; Facultad de Ciencias, UNAM; Sociedad Latinoamericana de Acarología, 2006.

Results of the biofacies analysis led to recognition of four mite-bearing biozones and one zone devoid of mites, and it was shown that biofacies boundaries were not coincidental with sediment contacts (Erickson et al., 2003). When the habitat groups of each biofacies are analyzed as percentages of the total mite count in each biofacies and plotted, they produce a visual means for recognizing dominant elements of habitat. The concept is similar to the isoalent groups of Knülle (1957) as employed by Schelvis (1990, 1998) although our group assignments are more subjective. Figure 8 relates the groupings sequentially and includes interpretations of habitat inferred from the mites.

The biofacies approach is useful when the sedimentary section is homogeneous, particularly if it is all peat, so there is little direct interpretation to be made from changes in sediment type. Oribatid assemblages that have been used stratigraphically to define biofacies demonstrate variations in depositional environment that are otherwise masked within

sedimentary sections (Erickson et al., 2003). Species assemblages subdivided by habitat preference yield further information about environmental change (Table 1; Figure 8) and thus paleoclimate.

Paleoclimate Proxies

Virtually all types of fossil oribatid studies offer information about paleoclimate. Many interpretations are second or third order inferences that fall out of assemblages of fossil species (Figure 8) and their habitat preference data rather than originating as direct proxy applications. Oribatid studies designed to provide direct first order proxies of temperature and moisture are becoming more common although the results they produce will continue to be semiquantitative or qualitative until physiologic limits for the modern fauna are better known (Behan-Pelletier and Bissett, 1994; Behan-Pelletier and Eamer, 2007). Multiproxy studies of Holocene deposits are providing

increasingly more refined paleoclimate and climate change information (Larsen et al., 2006; Sidorchuk, 2004). We will describe some examples below.

Proxies of temperature and moisture – lake and bog deposits

Close sampling of a 2-m section of core from Glovers Pond (Figure 9) known to contain the Younger Dryas cold interval was designed to use counts of the aquatic mites *Hydrozetes* spp. (Figure 10), the *Sphagnum* mite *Limnozetes* cf. *rugosus* (Figure 11), and terrestrial species (Figure 12) to define biozones that were climate-controlled (Erickson and Solod, 2007). Productivity of the lake and lake shore environments in postglacial Glovers Pond was temperature-driven and oribatid populations responded to warmer temperatures by increasing their numbers independent of sediment types as seen in Figure 13. Subsequent interpretation of biozonation was based upon synchronous changes in mite numbers as proxies of climate (Figure 14). C^{14} ages bracket the study

interval and temperature fluctuations were verified by O^{18} isotope analyses (Quevedo et al., 2002).

Some of the fossil oribatids that frequently occurred in Glovers Pond biozones include those in Figure 15. Declines in productivity included oribatid populations that are not aquatic, or semiaquatic, suggesting the data reflect climate changes large enough to influence all habitats, as opposed to short-duration drought or wet episodes. Oribatid biozones are interpreted to indicate established postglacial climate intervals from the Allerød through the Preboreal Oscillation into the Holocene warming (Figure 14). A sudden decline at 619 cm depth is believed to correlate with the Gurnensee/Killarney cold event recorded in only the best of stratigraphic records.

We believe that there is a great deal more information contained in these data (Figure 14) an example of which is our observation that within the cold interval of the Younger Dryas (Zone B) there is a cold, damp interval (612–581 cm

Figure 14 Interpretation of paleoclimate intervals based on distributions of oribatid mites zoned by population structure. Oxygen-isotope data from C-I-4 provide independent temperature proxy. The top of the Younger Dryas (Zone B) may be unconformable with the Preboreal. Modified from Erickson JM and Solod AM (2007). Recognition of postglacial cold intervals by quantitative biozonation of fossil oribatid mites. In: Morales-Malacara JB, Behan-Pelletier V, Ueckermann E, et al. (eds.) *Acarology XI: Proceedings of the International Congress*, pp. 9–16. Mexico: Instituto de Biología, UNAM; Facultad de Ciencias, UNAM; Sociedad Latinoamericana de Acarología, 2006.

depth) of fluctuating temperatures followed by a stable, cold, dry interval (Erickson and Solod, 2007). The cold damp interval itself may be partitioned by a dry episode at approximately 601–603 cm depth. A second example is found at 557 cm when recovery from the Preboreal Oscillation cold event began, first by an increase in terrestrial taxa and then *Sphagnum*-dwelling *Limnozetes* populations, followed in 6 cm by an increase in populations of *Hydrozetes* spp. We interpret these

data to mean that the Preboreal Oscillation was dry and cold, and as climate warmed, moisture levels also increased, but slowly. Terrestrial productivity improved as groundwater levels rose and *Sphagnum* production returned in bogs, but lake level did not return to normal for a considerable time. This recovery contrasts with several earlier episodes in which aquatic and semiaquatic species recover in consort. Fossil specimens illustrating examples from each biozone are included in Figure 15.

Proxies of temperature and moisture – cave deposits

An unusual setting for oribatid study was described by Polyak et al. (2001). Oribatids were discovered within laminations of two stalagmites in Hidden Cave, a New Mexico cavern in the Guadalupe Mountains. To determine similarity with modern conditions a study of the living fauna of the cave environs was conducted. It was then compared with the 11 oribatid fossil taxa of the stalagmites which was a mismatch. Wetter and cooler suggested by presence of *Epidamaeus* (*Epidamaeus*) sp. implied that pine forests now existing at higher elevations were likely present at the cave elevation during formation of the stalagmite intervals examined, 3135–887 years BP.

Taphonomic Analysis

Study of the causes of death and fossilization of organisms, biostratinomy, are often focused on the events of transport and interment of fossils that leave a 'taphonomic imprint' on the fossil. When mites are considered fossil, the study of how they became so is legitimized as it were. Every fossil has a taphonomic history and each is potentially unique. Erickson (1988) examined hundreds of fossil mites during the course of picking them from core samples, and he recognized that preservation characteristics varied stratigraphically. He presented a description of the variation in the form of a Taphonomic Scale (Figure 16) of oribatid preservation condition (Erickson, 1988). He recognized that because the starting condition of the fossil is known, the endpoint it arrived at can be used to infer some of the geologic processes that acted on the corpse on its way to the deposition site. Drouk (1997) also discussed the concept.

Recognition of unconformities

Solod (2001) included study of taphonomic condition of mites through a study section of core from Glovers Pond. Mites were classed and ranked from 1 to 5 (Erickson, 1988) then indexed by taxon and interval using a simple formula. For example, the number of *Hydrozetes* spp. of each class multiplied by the class rank and added for all classes present in the sample is divided by the total number of fossil mites in the sample thus giving a value between 0 and 5 which is graphed by taxon and stratigraphic interval (Figure 16). The value serves as a Preservation Index that can be related to the scales of mite condition and used for stratigraphic comparison. Results are not fully interpreted, but Erickson has noted that there is tendency for fully-compressed or sediment-filled specimens to occur in restricted units near or at interfaces overlain by offlap-onlap depositional cycles. Furthermore, sediments filling the class 2 mites are often organic matter although the specimen may be originating from marl when exhumed. Class 3 mites are thought to have been compressed by compaction of sediments resulting from lowered water tables in basin-margin peatlands.

In one such interval, 569–557 cm, there is some evidence the oribatids have been reworked from an eroding basin-margin peat, or soil horizon, exposed by prolonged low water conditions and redeposited both in upper sediments of the declining-water phase and in basal sediments of the rising-water phase centered on the Preboreal Oscillation (Figures 14 and 16). The Preservation Index alerts us to the condition

of potential unconformity with as much sensitivity as do the numbers of mites to temperature and moisture-level changes (Figure 14). Application of this Taphonomic Scale and the Preservation Index to entire stratigraphic sections may make it possible, or easier, to assess unconformable relationships concealed within lacustrine cores. In many instances these are difficult to recognize by sedimentologic examination alone. Greater study of mite taphonomy is in order.

Archaeological Research Applications

Some of the earliest uses of fossil mite data were made by archaeologists in order to evaluate environmental conditions associated with prehistoric settlements that may have been influenced by climate change or environmental crises. As described above, Denford (1978), Schelvis (1987, 1989, 1990, 1992, 1997, 1998), and Schelvis and Van Geel (1989) pioneered application of oribatid and predatory mites for understanding habitat conditions related to archaeological sites. Fossil oribatids are underutilized in this discipline.

Socio-economic patterns

In 2007, a group led by Chepstow-Lusty reasoned that socio-economic conditions at a site in the Andes were linked to the size of domestic animal populations locally. Oribatid populations were suggested to be enlarged in response to larger amounts of dung present in grazing yards from whence it was also washed into a nearby lake. Mites from the yard were also washed into the lake and deposited. Lake waters likely suffered eutrophication at the same time as there were increasing populations of aquatic oribatids. Chepstow-Lusty et al. (2007) found three taxa, *Galumna* sp., *Trichoribates* sp., and *Hydrozetes* sp. present in sufficient numbers in cored lake sediments to allow quantitative evaluation of fossil populations. These data demonstrated three episodes of enhanced animal productivity interspersed with two episodes of reduced domestic productivity over the past 1200 years. The authors called for additional study of mite taphonomy and local community structure and composition.

Spring deposits

As awareness of fossil oribatids expands, so too will their applications. The well-studied Quaternary deposits at Florisbad, South Africa, include disturbed paleosols as old as the last interglacial, eolian silts and spring deposits as young as Middle Stone Age (MSA). They have been studied for numerous paleontological and archaeological factors. To this knowledge Coetzee and Brink (2003) have recently added data on fossil oribatid and mesostigmatid mites, some as old as 125 000 years BP. It was noted that most of the species found were able to reproduce parthenogenically which suggest that they were aquatic species. Thelytokous mites are currently being investigated by R. A. Norton in an effort to understand ecological advantages of this, and other, oribatid reproductive modes (Norton and Palmer, 1991). Coetzee and Brink's oribatid data permitted more accurate interpretation of organic sediments of the MSA horizon which contained *Papillacarus capucinus*, suggesting they are more likely related to organics produced in the spring than to eolian sedimentation (Coetzee and Brink, 2003).

Figure 16 Oribatid taphonomic scale (Erickson, 1988) includes five recurring types of preservation; classes 1–4 are gradational to some extent with class 1 being inflated and pristine, class 2 somewhat inflated with setae preserved but missing some plates and mouthparts thus leading to filling body cavity with sediment, class 3 flattened, complete skeletons, class 4 complete prodorsal and ventral shields but notogaster, genital, and anal plates missing, class 5 prodorsal region only suggesting predation of hysterosoma. Inset is graphic display of Preservation Index data from Glovers Pond core C-I-4 after Solod (2001). Data for Glovers Pond core C-I-4 with depth in centimeters after Solod (2001).

Acknowledgments

This article draws heavily on the works of acarologists and paleoacarologists throughout the world, and we are most appreciative of their efforts although space limits prohibit more complete analysis of all contributions. Assistance over many

years from R. Laub and the Buffalo Museum of Science, from D. Waters, R. Metzger, D. Jennings, A. S. Solod, and St. Lawrence University paleoacarology students, from S. J. Carpenter and H. Quevedo of University of Iowa, and from J. Schelvis, R. A. Norton, and V. Behan-Pelletier are gratefully acknowledged.

Some History

Pollen analysis or palynology lies at the interface of geology and biology but has close contacts with other disciplines such as archaeology. Pollen analysis has tended to develop in different directions in different countries, largely dependent on the interests of the influential pioneers in the field. The study of Quaternary vegetation history began in Scandinavia, at the end of the nineteenth century, primarily through the work of Blytt

and Sernander, botanists who examined peat bog stratigraphy and plant macrofossil content to develop a scheme of postglacial climate change. Their ideas were further developed by the Swedish geologist [von Post \(1916\)](#) with the technique of statistical pollen analysis that is the most widely used method for reconstructing Quaternary vegetation history today. Von Post attracted other scientists to the field, including the Swedish botanist Gunnar Erdtman, who through his international outlook and subsequent work on pollen morphology and

preparation technique deserves to be widely remembered. Erdtman was the first to publish widely on von Post's methods outside Scandinavia and paid an influential visit to Scotland, Ireland, and the Isle of Man in the mid-1920s. However, he was long overshadowed by von Post and was unable to obtain a research position in Sweden until late in his career. Consequently, Quaternary palynology in Sweden has tended to be carried out within the Earth sciences (Traverse, 1988).

In Denmark, the pioneer palynologists (Iversen, Jessen, and Troels-Smith) were based at the Geological Survey, National Museum, and Botanical Institute and helped develop the interdisciplinary nature of Quaternary science. Jessen brought palynology to Ireland. The links to botany and forest ecology were strong, with the Danish Geological Survey being a major force for forest conservation. The establishment of an experimental field station at Draved Forest, Jutland, in 1949 was a landmark. At the Geological Survey, Iversen created a department with a strong international reputation that was a formative influence on the later development of the subject in the United States, as both Cushing (Cushing and Wright, 1967) and Davis (1976) studied in Copenhagen. Iversen linked with the Norwegian botanist Faegri to produce a major textbook of pollen analysis in 1950, now in a fourth but aging edition (Faegri and Iversen, 1989). Birks (2005) has reviewed the interesting development of pollen analysis in Scandinavia.

Erdtman inspired, among others, Godwin to work on the East Anglian fens and submerged forests of coastal peat beds. Godwin (1934) published a critical assessment of the potential of von Post's methods and dominated the British paleoecological scene between 1940 and 1960, becoming Professor of Botany at Cambridge and founding a great British centre of botanical paleoecology. *The History of the British Flora*, a factual basis for phytogeography (Godwin, 1975), first published in 1956, is still a useful paleoecological text summarizing early pollen work in Britain. He emphasized the close links between pollen and plant macrofossil studies. Pollen studies developed somewhat independently in Central and Eastern Europe with Rudolph, Bertsch, and Firbas being important names among the pioneers. Auer was influential in both Finland and Canada and von Neijstadt in the Soviet Union. The contributions of many of these early scientists are reviewed by Lang (1994). Sears, Potzger, and Wilson were important founders of North American Quaternary palynology (Canright, 1995).

The schools set up by Firbas (1949) in Central Europe and Godwin in England collected enough data to enable the reconstruction of vegetation and environmental change on a far larger scale than had been hitherto attempted. Godwin's initiatives were developed at Cambridge by West, who exemplified the geological aspects while Birks and Birks (1980) developed the biological links. In Poland, Szafer, director of the Botanic Garden in Cracow, began a series of studies of the Quaternary flora of Poland as early as 1912. A fortuitous meeting with botanist Tansley from Britain, on an excursion to Poland and Czechoslovakia in 1928, led to an invitation to participate in the International Botanical Congress in Cambridge in 1930, where he contributed to the symposium on the distributional ecology of beech. His interests were very wide-ranging and included both pollen and macrofossils, and he first demonstrated the value of isopoll maps in studying the Holocene history of beech and spruce in Central–Eastern Europe (Szafer, 1935).

Recent Developments

Von Post (1916) and Godwin (1934) speculated about the ways in which the study of vegetation history could contribute to the biological sciences. Many of these speculations have subsequently become reality, and the results are outlined in the articles that follow this introduction. After the initial enthusiasm and excitement from the pioneer days of palynology, a significant development was the routine application of independent chronologies to Late Quaternary sedimentary sequences through the development of radiocarbon dating (Taylor, 2000). This development took place during the 1960s, in research groups with access to sufficient funding, and contributed to a generally increased level of precision in the reconstruction of vegetation. With independent dating for the Holocene, it was possible to make meaningful comparisons within and between regions and eventually build databases that made pollen data accessible to a broad range of scientists. Quaternary pollen analysis developed from being merely a method of geological correlation into a useful tool for exploring vegetation dynamics.

Davis (1976) and Huntley and Birks (1983) published continental scale maps showing the Holocene spreading of tree taxa from their glacial refugia to their present distribution. Their work illustrated the dynamic nature of tree distributions that have undergone continuous change. The subsequent work of the COHMAP (Cooperative Holocene Mapping Project) group (Wright et al., 1993) demonstrated that vegetation was continuously changing in response to climate forcing, bringing into focus the quasi-equilibrium situation between vegetation and climate. This line of research, which originated in a strictly geological approach, has led to a paradigm shift in biology. The concepts of climax vegetation and traditional succession were shown to be largely untenable under typical disturbance regimes with a constantly changing climate. Rather, the research suggested that plant species acted in an individualistic manner, leading to temporary assemblages of plants in vegetation communities that are nevertheless recognizable in the pollen records. This development in the subject is a good example of results from one discipline leading to constructive development in another – the best possible outcome of interdisciplinary research.

Increased awareness of the role of climate change gave a new impetus to palynological research, beginning in the 1980s. Pollen data provided evidence for the impacts of constant climate change and are used as one proxy among many for the reconstruction of past climate. A complicating issue is the undoubted impact of human activities on vegetation during recent millennia that is well recorded by pollen data, and considerable progress has been made in placing archaeological sites in a broader environmental setting. Identifying and assessing the relative importance of the varied drivers of long-term vegetational change is proving to be one of the current directions of palynological research.

Pollen diagrams have tended to increase in length and detail over the years, with more types identified and increased precision in all aspects of the work that has transformed the nature of the subject. In a landmark paper, Davis (1963) made an important attempt to relate pollen spectra in a more quantitative manner to its source vegetation through the development of R-values. Her work laid the foundation for later developments in pollen representation theory that are now culminating in

practical tools for the quantitative reconstruction of vegetation at various scales (Gaillard et al., 2008; Prentice, 1985; Sugita, 1993). Increasing quantitative precision has stimulated the application and development of new statistical analytical tools to pollen data that were summarized by Birks and Gordon (1985) and are reviewed in Numerical Analysis Methods.

The increasing quantitative and spatial precision in vegetation reconstruction has led to exciting new insights being generated in the research areas of evolution, ecology, and conservation biology (Bennett, 1997). These topics included plant migration, disturbance biology, population ecology, and the long-term evolution of genetic structure. The development of the Long-Term Ecological Research program has brought into focus the value of longer timescales in the understanding of the current status and direction of change of biological systems, which has increased the interest of biologists in palynological research (Willis et al., 2010).

Variable Scales: A Special Feature of Pollen Data

A unique feature of pollen analysis is the flexible way in which the method generates data at different spatial and temporal scales (Figure 1). Traditional pollen analysis utilizes pollen preserved in lake basins and peatland sites to study the effects of climate change and anthropogenic influence on vegetation. Increasing the temporal resolution with annually laminated sediments allows short-term events to be resolved and permits time series analyses to be made with ease. Choosing sites with longer sedimentary sequences from unglaciated regions yields the long-term records that cover more of the Pleistocene and allows comparison with marine and ice core records. The same analytical techniques can be applied at fine spatial scales to describe vegetation

succession after a local fire or record the effects of death of a single tree in a mor humus profile. The pollen analyst has a unique set of controls at the fingertips with which to manipulate temporal and spatial scale and study a wide range of processes.

Pollen analysis has been joined over the years by a range of other analytical methods using the same sediments to generate more complete environmental reconstruction. Some of these other methods are covered in this section, including phytoliths, charcoal, and ancient DNA. Pollen, analyzed together with plant macrofossils, beetle remains, diatoms, chironomids, and other biological, physical, and chemical analyses, comprises multiproxy data that are used to make reconstructions of climate and the biological and physical environments that are as complete as possible.

Key Insights from Pollen Analysis

The articles that follow document a range of insights into the nature of vegetation dynamics obtained from pollen data. A few of these are highlighted here.

Nonanalog plant communities are unique assemblages of plants that no longer grow together. Examples are the ash–ironwood (*Fraxinus–Ostrya*) communities of the midwestern United States during the Late Glacial and the rich deciduous forests with pine found in the mid-Holocene in northwest Europe. The American example is thought to reflect the unique combinations of climatic parameters occurring at that time, while the European example has been lost due to almost complete anthropogenic modification of natural forest communities.

Individualistic dynamics of tree distributions during the Holocene have been of major importance to the development of plant

Figure 1 The spatial and temporal scales available to the pollen analyst.

Figure 2 Converted pollen accumulation rates (left column) and modeled biomass (right column) for each species, at Tsuolbmajavri (top row, 68.69° N 22.08° E), Abborrtjärnen (second row, 63.88° N 14.45° E), Holtjärnen (third row, 60.65° N 14.92° E), Sweden, and Laihalampi, Finland (bottom row, 61.49° N 26.08° E; Miller et al., 2008).

Figure 3 The changing area of Fennoscandian forest cover during the Holocene. Forest is divided into six categories. The diagram covers about 0.7% of global land area and is based on 308 individual pollen diagrams. The x-axis shows the area covered by each forest type, and one unit is approximately 7500 km².

ecological theory. Species have tended not to migrate in biomes or communities but rather in response to individualistic environmental forcing, although [Clark and McLachlan \(2003\)](#) show that intersite variance for Holocene tree abundances in North America tended to stabilize rapidly, showing that plant distributions cannot be explained by individualistic behavior alone but include a component of community dynamics.

Refugial theories have developed to help explain present patterns of genetic diversity and the regionally variable loss of species during periods of rapid climate change and climatic extremes. The links between paleoecology and evolutionary genetics are rapidly developing, with vigorous debate about the locations, nature, and abundance of these refugia. European refugia appear to have had different characteristics to those in North America with consequences for the long-term survival of species.

The quasi-equilibrium of vegetation with climate has been debated among palynologists for many years. Large international projects and syntheses have concluded that pollen data can in many situations be used as a proxy for climate data and that the concept of 'migrational lag' or delayed response of vegetation to climate change caused by dispersal limitation is either of short duration or not easily detected in the pollen record. European beech for example was slow to dominate in the European Holocene, but its dynamics are broadly consistent with its relationships to regional climate ([Bradshaw et al., 2010](#)).

The extent of human influence on vegetation is considerable but varies both temporally and spatially. In many parts of the world, human influence is now a more important driver

of vegetational change than climate, but this is most likely to be a relatively recent development. Restoration ecology is consequently an emerging topic that is influenced by the paleovegetational record ([Jackson and Hobbs, 2009](#)). Human influence does extend far back in time, primarily through its effect on fire regimes and populations of large browsing and grazing animals. Pollen analysis has always had a close link to environmental archaeology and has contributed to placing archaeological sites in a broader environmental context.

Invasions of new and exotic species are a major concern within nature conservation. Pollen analysis has documented the spread and invasion of species in the past and provides insight into the invasion process and population growth, and their long-term consequences. The spread of hemlock (*Tsuga canadensis*) into the midwestern United States showed an interesting balance between dynamics and stability at a fine spatial scale, while the spread of spruce (*Picea abies*) through Scandinavia was associated with competitive replacement of lime (*Tilia cordata*) and a recent uniform spreading rate of about 250 m year⁻¹ in Sweden ([Bradshaw and Lindbladh, 2005](#); [Seppä et al., 2009](#)).

Disturbance biology is another topic where pollen analysis has contributed to biological understanding and long-term ecological research. Periodic disturbance by fire is documented by paleoecological techniques, while chronic disturbance from animals can often be inferred. Fire has long been a major ecological factor in several ecosystems and has a complex relationship with human activity. There can be abundant charcoal remains in Quaternary sediment cores, and fire interacts with vegetation type to be a

major disturbance agency in the boreal region (Ohlson et al., 2011), although natural fire regimes are now rare in populated regions. The hemlock decline and elm decline are examples of the widespread impact of disease.

The interglacial–glacial cycle and its links to evolutionary biology is a topic where pollen analysis is altering the way scientists think (Bennett, 1997; Hu et al., 2009). The nature of the glacial–interglacial cycle and its biological consequences have been investigated for many years, and the relative importance of soil development, climate change and the biological properties of organisms have been intensively debated. Some interesting conclusions are emerging that have profound scientific implications. For example, it seems that most generation of genetic diversity predates the Quaternary, which is characterized by a general loss of diversity in, for example, woody plants (Willis and Niklas, 2004). Vegetation has usually tracked rapid climate change, but the response can be moderated by changing soil nutrients. History matters, and community structure is constrained and shaped by its past.

The Way Ahead

No one can be certain what the future will bring, but studies of the past dynamics of predictable systems do help us to build likely scenarios. One current development within pollen analysis is to use past reconstructions to test climate-driven simulations of vegetation. Models that can correctly simulate past vegetation are more likely to prove reliable in the future. There are a growing number of these validation exercises in progress, and they give pollen data an important role in forecasting possible consequences of future climate change. Data–model comparison has established that the northern distributional limits of temperate trees in Fennoscandia were controlled by millennial variations in temperatures during the Holocene (Figure 2; Miller et al., 2008).

The building of global databases of environmental data from the past and present is likely to continue. As pollen databases grow and improve in quality, there will be new analyses made on the basis of their content. Pollen data can be combined in innovative ways to represent vegetation cover from large areas. A composite forest type diagram has been drawn for the whole of Fennoscandia showing the area covered by six forest types throughout the Holocene (Figure 3) (Holmqvist et al., unpublished). Records of changing vegetation over large areas of the globe are useful tools in understanding global system dynamics and helping monitor the scale and consequences of human impact on terrestrial ecosystems.

Pollen analysis is moving from the era of primary data collection into the exciting phase of secondary data analysis. Pollen databases are building a new sense of community among palynologists and with pooled data of high quality, new insights into the nature of vegetation dynamics and its relationship to the dominant drivers of human activity and climate change await discovery.

Introduction

The study of DNA recovered from ancient plant material has had a short, but turbulent, history. Similar to other ancient DNA (aDNA) subfields, plant aDNA studies experienced early highs, with high-profile papers reporting the recovery of groundbreaking genetic material from samples that dated back millions of years. However, these reports from the early 1990s were quickly followed by disappointing lows, most notably the discovery that contamination problems plagued the results. Fortunately, by the late 1990s, the field staged a healthy recovery, and DNA from old plant material has now been used in a wide range of applications, from forensics to archaeology to ecology (Palmer et al., 2012). However, despite the interest, plant aDNA studies have lacked the focus that other areas of aDNA have achieved. For example, one review (Gugerli et al., 2005) notes that of a sample of almost 500 papers on aDNA published between 1984 and 2004, less than 60 (11%) dealt with plants. Furthermore, despite the power that aDNA studies of other types of biota have had to offer in the Quaternary context (cf. Willerslev and Cooper, 2005), plant aDNA has remained essentially unexploited. This is a pity, because conventional terrestrial paleoecology relies predominantly on plant remains (e.g., pollen and spores), thus fossil plant material is abundant and detailed paleoecological information is available for hypothesis testing using aDNA.

The Recovery and Analysis of Ancient Plant DNA

Ancient DNA

The term aDNA can be used to loosely describe DNA that is preserved in, or recovered from, any nonliving source that has not been specifically preserved at the time of death or sampled for genetic analyses. Characteristically, such DNA will have undergone some degree of degradation, resulting in both reductions in the overall yields and limitations on the size of analytical fragments. As such, there are limits to the analytical techniques that can be applied to aDNA. Many methods that are currently becoming popular in studies on modern DNA require better quality DNA than can be recovered from aDNA specimens. For most of the aDNA field's history, researchers developed their analyses to focus on the amplification of short <500 base pair (bp) fragments of DNA using the polymerase chain reaction (PCR). One of the key features of PCR is that particular genes or genetic areas can be targeted in order to answer research questions. Often, genetic regions can be chosen so as to be either unique to the species of interest or conversely shared among a variety of related taxa, enabling the exclusion, or inclusion, of different original sources of

DNA from the analysis. For example, studies that aim to identify to which species or taxonomic group a particular sample belongs must find a suitable genetic sequence that is known to be variable between potential source taxa, in such a way that if the sequence can be recovered from the questionable sample, and it matches a sequence obtained from the candidate sources, the identification can be made. Studies that are focused on the phylogenetic relationship between specimens or those that investigate population-specific factors also rely on markers that can discriminate individuals and taxa. However, these studies also face the requirement of containing enough informative data that can be combined with computational analyses to resolve the questions.

Genetic Regions Analyzed

In comparison to animals, plant genomes offer an increased number of distinct genetic targets for analyses. Plant genomes are comprised of three unique components: mitochondrial DNA (mtDNA), chloroplast DNA (cpDNA), and nuclear DNA (nuDNA). All three have been investigated in plant aDNA studies, although not in equal frequency due to various strengths and weaknesses. Most plant cells contain multiple copies of mtDNA and cpDNA, thereby increasing the chance of their recovery from ancient samples. However, plant mtDNA is not frequently used in aDNA research, because unlike animal mtDNA, it frequently recombines and has a very slow mutation rate. In contrast, cpDNA does not recombine and evolves more quickly, albeit still at a fourth of the rate of nuDNA. Therefore, cpDNA is particularly useful for aDNA in taxonomic identification and phylogenetic analyses, commonly using the *rbcl* gene and *trnL* intron. Taberlet et al. (2007) have recently proposed the chloroplast *trnL* (UAA) intron as a candidate for genetically 'barcoding' modern plants. In principle, a barcode is a genetic region with a unique sequence for every species. Like barcodes on commercial products, a quick analysis can yield the exact item, or in this case, taxon. This approach has become popular in many branches of biology, because it allows researchers to identify the taxonomic affiliation of unknown samples. The chloroplast *trnL* (UAA) intron may serve as such a DNA barcode for plants because it has sufficient variability to distinguish between many species and genera, while still having conserved flanking regions for PCR amplification in all plant families. Furthermore, the P6 loop of the intron is short enough (10–143 bp) to be appropriate for aDNA research.

Compared to mtDNA and cpDNA, plant cells contain very few copies of nuDNA. However, nuDNA codes for the phenotype of the plant and therefore has been used to understand various functional properties of ancient specimens (e.g., Jaenicke-Després et al., 2003). Microsatellites (short repeated sequences of variable length) in nuDNA have also been studied

to understand relationships between varieties of a species, such as grapes (Manen et al., 2003). Another important feature of the nuclear genome is polyploidy – the trait of having more than two pairs of homologous chromosomes per cell. Polyploidy often leads to important phenotypic changes, especially for agricultural crops. Naturally, it is an important concern for aDNA research. However, it is challenging to determine the number of copies of a chromosome given the degraded nature of ancient samples. Rather, researchers have investigated this topic through the use of markers unique to each polyploid type (e.g., Blatter et al., 2002).

Source Materials Analyzed for Ancient Plant DNA

Naturally Occurring Source Materials

Many different source materials are available for ancient plant DNA studies. All plant cellular tissues contain DNA, and thus, any that can be found preserved *postmortem* are of interest. Plant material represents the bulk of the global necromass (the weight of dead organisms), and as such, a large amount of naturally preserved material exists that can be exploited in aDNA analyses. Much of this material can be visually identified as plant matter (see [Plant Macrofossil Introduction](#)) such as leaves, woods (e.g., Dumolin-Lapegue et al., 1999; Liepelt et al., 2006), or pollen (e.g., Paffetti et al., 2007; Parducci et al., 2005). Other studies, however, have successfully recovered ancient plant DNA from samples where visual identification is impossible – including permafrost and sediment cores (Figure 1) dating back several hundred thousand years (e.g., Willerslev et al., 2003, 2007), human and animal coprolites, some which date back nearly 30 thousand years (e.g., Poinar et al., 1998; Figure 2), packrat middens (Küch et al., 2002), and even from within the colon of mummified specimens (Rollo et al., 2002). Although the above are limited to samples less than 800,000 years old, claims have also been made for the recovery of much older DNA – from samples that date back millions of years.

However, as discussed in more detail below, it is likely that the DNA recovered from such ancient remains was probably derived from modern contaminants, and as such, the oldest yet authentic DNA recovered dates only as far back as 450,000–800,000 years (Willerslev et al., 2007). Furthermore, other potentially useful sources of ancient plant DNA remain to be exploited. The successful recovery of DNA from sediment and permafrost cores suggests that authentic plant aDNA might be expected to survive in stable anaerobic environments, such as sediments found at the bottom of certain lakes (Gugerli et al., 2005) and other marine environments, as well as in semi-permanent ice, such as permafrost (Willerslev et al., 2003) and ice sheets (Willerslev et al., 2007).

Herbarium Collections

In addition to naturally preserved material, many other sources of DNA are available for use in ancient plant DNA studies. Globally, herbariums contain vast amounts of dried or otherwise preserved specimens that may often contain preserved DNA (cf. Drabkova et al., 2002; Saltonstall, 2002). It is worth noting that studies using herbarium specimens have not been limited to plant DNA. Several interesting studies have also

reported the recovery of historic plant pathogen DNA from herbarium specimens, including that of the potato blight strains (*Phytophthora infestans*) dating as far back as the Great Irish Famine of 1845, recovered from dried potato specimens (e.g., Ristaino et al., 2001), and of the bacterium *Xanthomonas axonopodis* pv. citri from historic citrus canker specimens, some of which were more than 90 years old (Li et al., 2006).

Archaeological and Historical Collections

Plant tissues and secondary products have played an important role in human society. A wide variety of preserved materials have been demonstrated suitable for DNA-based study. Examples include wood used for building construction, furniture, cultural and other historical artifacts (e.g., Burger et al., 2000; Deguilloux et al., 2002), and papyrus (Marota et al., 2002). Seeds of cultivated plants from numerous archaeological sites have been studied, including wheat (*Triticum* spp.; e.g., Allaby et al., 1999), maize (*Zea mays*) (Figure 3; e.g., Jaenicke-Després et al., 2003), and various grape (*Vitis vinifera*) varieties (Manen et al., 2003). Plant DNA has also been recovered from the interior surfaces of waterlogged amphoras, thereby revealing past contents (Hansson and Foley, 2008). It is even possible to isolate and identify genetic sequences directly from archaeological sediment (Hebsgaard et al., 2009). The source of the so-called ‘dirt’ DNA is for the most part unclear. However, Tanaka et al. (2010) claim to have recovered DNA from plant phytoliths isolated from archaeological sediment samples (but see Elbaum et al., 2009). (For a more detailed discussion of plant DNA as it pertains to archaeology, see Schlumbaum et al.’s (2008) thorough review.)

The Scope of Ancient Plant DNA

Plant Domestication

Due to their relevance in human history and their fundamental position in human society, a large portion (almost 50% of studies assessed in a recent comprehensive survey by Gugerli et al., 2005) of plant aDNA studies have focused on agricultural species. One key area of research is the history of plant domestication, using the large quantities of well-preserved and accurately dated material that is found in many archaeological sites (mostly no older than a few thousand years). The genetics of modern crops has been extensively studied, and as such, many molecular markers developed in those studies have been useful in the archaeogenetic context (Brown, 1999) to investigate such questions as the origin and spread of agriculture in species that include maize (*Zea mays*; Freitas et al., 2003; Lia et al., 2007), bread wheat (*Triticum aestivum*; Li et al., 2011), the bottle gourd (*Lagenaria siceraria*; Erickson et al., 2005), and *Vitis vinifera*, the wine grape (Manen et al., 2003). Furthermore, some studies have even investigated the selection undergone in the genome of such crops. For example, by using phylogenetic methods and DNA recovered from a variety of modern and ancient specimens, Allaby et al. (1999) were able to investigate the evolution of the high-molecular-weight glutenin gene family and, using their results, argue that Emmer wheat (*Triticum dicoccum*) may have been domesticated on two separate occasions. While that study provided insights into evolution

Figure 1 DNA from permafrost and soil. (f) Soil samples taken from Scladina Cave in Belgium for aDNA analyses using sterile conical centrifuge tubes (Photograph by Jonas Binladen and Eske Willerslev).

prior to the selection imposed by humans during domestication, other studies actually investigated evolution during the domestication process. For example, using archaeological samples spanning a range of dates (Figure 3), Jaenicke-Després et al. (2003) obtained DNA sequences from three genes (one involved in the control of plant architecture, one in storage protein synthesis, and one in starch production) that were hypothetically selected for (either deliberately or incidentally) during the domestication of maize and provide insights into the timing and sequence of selection on those characteristics. In a similar fashion, Palmer et al. (2009) have used aDNA to uncover the surprising origins of Egyptian two-rowed barley (*Hordeum vulgare* ssp. *vulgare*). They found that, despite having a more primitive morphology, the barley evolved from the derived six-row form and may have been perpetuated due to adaptations to local environmental conditions.

Population Paleogenetics

An additional area where plant aDNA has begun to play an important role is in population paleogenetics, that is, analyses that investigate how species or related taxa are genetically

changing through time. On a relatively recent scale, herbarium specimens of the common reed (*Phragmites australis*) have been used to reconstruct the timing and route of invasion into North America by a nonnative genotype during the twentieth century (Saltonstall, 2002). Specifically, by comparing two regions of cpDNA from non-North American samples collected prior to 1910 with those from modern North American specimens, Saltonstall (2002) demonstrated both that an introduction had occurred and that the introduced type (which is morphologically identical to the native) has displaced the native plant and even invaded previously uninhabited regions. On a deeper timescale, several studies have investigated nuDNA allelic diversity between modern and much older specimens, such as 4000-year-old seagrass, *Posidonia oceanica* (Raniello and Procaccini, 2002), to investigate changes in population diversity.

Bulked Specimen Analyses

Environmental reconstruction

In order to generate statistically meaningful results, studies such as those outlined above often require the analysis of DNA from multiple individual samples from different

Figure 2 Coprolite as a source of ancient plant DNA. Plant remains have been recovered from various coprolite sources, including 2000-year-old human (Poinar et al., 2001) (a) and 20 000-year-old ground sloth (Poinar et al., 1998) (b). Figure 3 DNA from archaeological maize. Archaeological maize cob from the Ocampo Caves (Valenzuela Cave), in northeast Mexico, dated to approximately 4000 years before the present (length, 47 mm). DNA from this and similar cobs has been used for aDNA studies on the domestication of maize (Jaenicke-Després et al., 2003). Reprinted from Jaenicke-Després V, Buckler ES, Smith BD, et al. (2003) Early allelic selection in maize as revealed by ancient DNA. *Science* 302: 1206–1208. Reprinted with permission from AAAS.

locations and time periods. Furthermore, should the research questions relate to plant communities as a whole, and not simply individual species, these methods are less than ideal. Recent developments in ‘bulk-screening’ techniques provide the means to effectively reconstruct past environments as well as investigate vertebrate diets from ancient coprolites (Tringali and Rubin, 2005).

Environmental reconstructions have so far been conducted using a variety of source materials, including glacial silt (Gould et al., 2010), marine cores (Paffetti et al., 2007), terrestrial sediment samples (Haile et al., 2007), rodent middens (Küch et al., 2002), and coprolites from ancient humans (Rasmussen et al., 2009) and extinct mammals (Poinar et al., 1998). Studies that present information about a range of coexisting plants are particularly exciting. For example, using samples from permafrost sediment cores dated between 10 000 and 400 000 years (Figure 1(a)–1(e)), Willerslev et al. (2003) were able to recover DNA sequences from at least 19 different plant taxa, providing insights into how the taxonomic diversity and composition of the Beringian vegetation changed over that interval. Among other things, this approach has several useful advantages in that as long as the cores can be accurately dated, and DNA preservation is adequate, DNA can be recovered from specific target points in time. Obviously, due to the somewhat stochastic nature of the fossil and archaeological record, this cannot always be achieved in other situations. An important question in sediment-based DNA studies is whether aDNA may have moved across stratigraphic layers. For example, Haile et al. (2007) investigated DNA leaching in dry sediments from a New Zealand cave and found evidence for downward migration of DNA.

Diet

Genetic analysis of desiccated feces – also known as coprolites – can be used to identify which organism produced the feces and what plants and animals formed its diet. Despite the corrosive nature of mammalian digestive processes, a significant amount of amplifiable DNA can be recovered from both recent and ancient coprolites. For aDNA studies, bulk screening of plants in coprolites presents a fascinating opportunity to better understand the diets of past mammals. For example, van Geel et al. (2008) tested feces found in the digestive tract of a

22 500-year-old Siberian woolly mammoth for the *rbcl* gene and recovered ten DNA sequences which were consistent with the plant macrofossil and microfossil remains in the coprolite. Bulk screening of ancient human coprolites is also feasible; however, apart from a handful of studies (e.g., Rasmussen et al., 2009), this approach has been arguably underutilized by the archaeological community. Indeed, the analysis of plant DNA within a coprolite can be readily tested in conjunction with the DNA of the individual who produced the stool (cf. Gilbert et al., 2008; Rasmussen et al., 2009).

Before attempting to recover plant DNA from ancient coprolites, researchers should be aware of a number of noteworthy limitations and caveats. First, coprolites frequently contain various chemical compounds which impede DNA extraction and inhibit PCR amplification. Second, it has recently become recognized that plant DNA which is not part of an organism's diet can be incorporated in coprolites through inadvertent swallowing of airborne and waterborne pollen (cf. Reinhard et al., 2008). This occurrence may complicate interpretations of past diets but conversely may aid environmental reconstructions by providing a snapshot of animal's habitat shortly before its death. Another critical factor in bulk-specimen research is the database used for sequence queries. In order to determine the taxonomic origin of a genetic sequence, computational searches must be made against DNA databases, such as GenBank, in order to locate the most likely candidate. Thus, taxonomic identifications are fundamentally limited by the scope of the database. On the other hand, it is possible to revisit old data as online databases grow larger. For example, Reinhard et al. (2008) reanalyzed plant sequences recovered from prehistoric human coprolites from Texas first reported by Poinar et al. (2001). With the aid of an expanded database, they found that some previously unidentified sequences matched plants with medicinal and hallucinogenic properties. A final concern in coprolite DNA research is that it suffers from stochasticity in the finding of samples, thereby limiting choice of time periods and species that can be studied.

Forensic and Archaeological Uses

Not all plant aDNA work is focused on population or evolutionary questions. Plant aDNA studies have also played a role in simpler identification studies, such as the forensic or archaeological uses of the identification, and even tracing and certification of plant products. Recent studies have included analyses on plant-derived foods and drinks (e.g., Manen et al., 2003), fibers and textiles (e.g., Burger et al., 2000), woods (e.g., Deguilloux et al., 2004), and psychoactive drugs (e.g., Mukherjee et al., 2008).

Problems and Limitations of aDNA Studies

Extraction of Amplifiable Plant DNA

As with all aDNA studies, several problems challenge this field of study and must be appreciated in order to gauge the possibilities offered by plant aDNA. One of the simplest issues is something faced by all plant DNA researchers and involves the difficulties associated with purifying nucleic acids from plant tissues. Plant tissues are generally richer in primary or

secondary metabolites (such as carbohydrates or phenolic compounds) than animal tissues. Furthermore, many of the plant tissues that preserve best in the archaeological or paleontological record (such as wood or charred seeds) naturally contain these inhibitors (Gugerli et al., 2005). On top of this, many man-made products (such as treated wood or fibers) have been treated with other products (such as dyes) that inhibit PCR. However, due to the commonplace nature of these problems in modern plant studies, they are not insurmountable. Future research will determine which existing methods to purify nucleic acids away from inhibitors are compatible with ancient samples. Instead, two much bigger problems seriously challenge plant (indeed all) aDNA studies, those of *postmortem* DNA damage and contamination.

The Credibility of Early Plant aDNA Studies

Questions about the credibility of results from aDNA studies arose almost immediately following the first publications of plant aDNA. In 1990, 770-bp-length DNA sequences were published that were attributed to 17–20-million-year-old fossilized plant cpDNA (Golenberg et al., 1990). However, although the fossils showed remarkable preservation, including cell structures such as the chloroplasts, and at first glance seemed ideal specimens, an attempt to replicate the results in a second laboratory failed (Sidow et al., 1991). Sidow et al. (1991) reported only the presence of high concentrations of high-molecular-mass bacterial DNA derived from living bacteria and suggested that the most likely origin of such DNA was through recent contamination during the excavation process. Furthermore, Pääbo and Wilson (1991) also expressed skepticism that a 770 bp sequence could be recovered after 20 million years. Based on laboratory calculations of depurination rates (and subsequent fragmentation) under hydrated conditions, these authors claimed that no sequence over 800 bp should exist after 5000 years, and nothing amplifiable should exist after 4 million years. Despite some counter arguments, and a few other studies in which researchers claim to recover aDNA from Miocene samples (e.g., Kim et al., 2004; Panieri et al., 2010; Figure 4), an overwhelming body of evidence now exists that suggests that Golenberg et al. (1990) did not successfully retrieve authentic aDNA sequences (cf. Hebsgaard et al., 2005).

The Postmortem Degradation of DNA

As the field of study has matured, it has become apparent that the scope of aDNA is limited by the *postmortem* degradation of DNA. Although *in vivo* DNA is protected by an array of repair mechanisms, *postmortem*, these cease to be active. Therefore, the damage processes that target DNA confer irreparable damage. The end result of most of these processes, which include, among other things, various oxidative and hydrolytic reactions, as well as cross-linking of the DNA to other molecules (including other DNA strands), is that the DNA rapidly becomes unsuitable for PCR, within days in extreme situations, but more often on the scale of years. At first, these limitations will simply be reflected through reductions in the number of templates available for amplification and the potential size of amplifiable fragments. Several studies on plant DNA

Figure 4 Examples of fossil plant material reported as a source of ancient DNA. Voucher photograph of fossil specimens used in an ancient DNA study claiming the recovery of Miocene *Magnolia* DNA sequences (17–20 Ma; Kim et al., 2004). (a) *Magnolia latahensis* (Berry) Brown. (b) *Persea pseudocarolinensis* Lesquereux. Many aDNA researchers believe that DNA is unlikely to survive for such a long time and would argue that the results are likely derived from contamination. Reprinted from Kim S, Soltis DE, Soltis PS, and Suh Y (2004) DNA sequences from Miocene fossils: An *ndhF* sequence of *Magnolia latahensis* (Magnoliaceae) and an *rbcL* sequence of *Persea pseudocarolinensis* (Lauraceae). *American Journal of Botany* 91: 615–620, with permission from Botanical Society of America, copyright 2004.

demonstrate this phenomenon. For example, Deguilloux et al. (2002) found an inverse relationship between amplification success rate and amplicon size in dry wood; smaller amplicons were present in larger numbers than longer ones due to degradation. The authors also demonstrated that, in the same samples, cpDNA, mtDNA, and nuclear ribosomal DNA (rDNA) genes could be amplified more often than single-copy nuDNA genes. This is consistent with DNA degradation, as individual cells contain multiple copies of cpDNA, mtDNA, and rDNA, and assuming DNA degradation affects all DNA sequences in a similar manner, these templates will out-survive those of the rarer single-copy nuDNA genes. Interestingly, the authors also found the same relationship when DNA content was investigated from young tissues from the outer part of tree trunks. That is, they are more likely to yield DNA, and yield larger fragments of DNA, than tissues from older heartwood samples (Deguilloux et al., 2002). Other researchers have approached the issue of *postmortem* degradation by searching for proxy measures of DNA preservation, thereby avoiding the testing of futile samples. For example, Elbaum et al. (2006) employed infrared spectroscopy to determine the amount of lignin in ancient olive pits and subsequently predict whether a given sample is likely to yield amplifiable DNA.

Impact of Specimen Age on DNA Survival

The implications of DNA degradation for any particular study depend largely on whether a sample is beyond the age at which DNA remains sufficiently intact and undamaged. Unfortunately, there is no simple answer to what this age is, because too little is known about *postmortem* DNA degradation (specifically which damage processes affect what specimens, in what combinations, and at what rates) to provide definitive answers. However, some estimates have been made, based on the knowledge that the rate of DNA degradation is inversely correlated with heat. Using calculated deamination and depurination kinetics for the four nucleotides, it has been estimated that under mammalian physiological salt conditions, neutral pH and an ambient temperature of 15 °C, 100 000 years is a likely estimate of the time beyond which DNA will be degraded to a level below the size of a useful amplifiable fragment (Lindahl, 1993). Under certain environmental conditions, however, such as encasement in ice or permafrost, this period may be extended by perhaps several times (Willerslev et al., 2003), while in warmer environments, the survival limit of amplifiable DNA is likely to be much shorter.

Problems Associated with DNA Degradation

DNA degradation presents several problems for the aDNA field (cf. Gilbert et al., 2005). First, researchers are limited as to the quantities of amplifiable DNA that they can recover. Second, due to DNA fragmentation and cross-linking, researchers are often limited in their ability to amplify templates of less than a few hundred bp in size (cf. Willerslev and Cooper, 2005). When this is combined with the insights about the implications of the relative abundance of different genetic targets, it becomes apparent that there are limitations on what can be achieved in this field of study. A further problem, and one that is most serious for the credibility of the discipline, is that of sample contamination. The low abundance of DNA extracted from a degraded specimen can easily be masked by modern DNA from external contaminants of the same or a similar DNA sequence. Without proper treatment to remove the environmental DNA, it is a very simple (and, unfortunately, common) matter to coamplify both sources of DNA. Depending on the relative concentrations of host-to-contaminant DNA in the PCR, the target DNA may be either completely swamped or sufficiently modified to result in erroneous data.

Contamination

Due to the multistep processes that are employed to successfully extract the low concentrations of DNA associated with ancient remains, contaminants can enter the system at many stages (cf. Roberts and Ingham, 2008). The most common sources of contaminants include the following:

Microorganisms. Most PCR reactions are based upon the hypothesis that primers will bind to specific loci not present in unrelated organisms, thus will selectively amplify only the DNA of interest. However, due to the potentially large numbers of genetically different, and as yet unsequenced, microorganisms that are estimated to exist, it is very difficult to

rule out the presence of short sequence homologues between the sample of interest and contaminant microorganisms in the environment.

Modern DNA introduced during sample collection. It is possible to inadvertently transfer modern DNA to ancient samples during field collection or later analyses. Therefore, it is recommended to collect and analyze plant aDNA samples with sterile equipment while wearing examination gloves. Although it has been shown to be advantageous to collect hominin fossils while wearing full body suits (Fortea et al., 2008), such a complicated procedure is not common for ancient plant collection and may be unnecessary because human contamination can be readily identified and ignored in ancient plant studies. In contrast, food particles and plant-based textiles are more problematical sources of contamination for plant aDNA research.

Sample conservation or other treatments. Many archaeological or historical collections may have been treated with glues and varnishes containing some plant-derived products and thus provide a contaminating DNA source.

Related specimens. It is possible for tissue or DNA extracted from one specimen to cross-contaminate others extracted in the same laboratory. In this case, both sources are coextracted; PCR primers may bind equally well to the authentic and contaminant sequence (or in the worst case, preferentially to the contaminant), and thus coamplify.

Previously amplified PCR fragments. The exponential nature of PCR results in huge numbers of amplified products (amplicons) concentrated into tiny volumes, which may spread rapidly and contaminate ancient samples with DNA, swamping the authentic aDNA. In addition, high levels of contamination can persist in a laboratory environment for long periods of time. Consequently, it is essential that all aDNA work be conducted in a dedicated clean laboratory far removed from amplified DNA. Furthermore, aDNA labs are required to be designed in ways to minimize outside contamination (Willerslev and Cooper, 2005).

Future Directions

Next-Generation Sequencing

Plant aDNA research is arguably on the cusp of being transformed through state-of-the-art technologies collectively known as next-generation sequencing (NGS; Palmer et al., 2012). NGS is quickly changing how DNA is studied in many fields, including aDNA. Most NGS platforms operate by isolating hundreds of thousands of fragments of DNA, and then sequencing each fragment in parallel. In this way, NGS platforms, such as Roche/454 FLX series, Life Technologies SOLiD series, and Illumina Genome Analyzer series, are capable of generating data in the magnitude of hundreds of millions to billions of nucleotides in a single run (Millar et al., 2008). In addition to yielding several orders of magnitude more data than PCR, NGS also retrieves shorter DNA sequences than is possible with conventional methods; PCR is normally used to amplify DNA fragments at least 60 bp in length, while NGS can recover DNA segments as short as 25 bp. Many other fields view this as a limitation, but it is a boon for aDNA research (Figure 5). As discussed previously, ancient samples generally yield many short DNA fragments and relatively few long

fragments; taken to the extreme, NGS can recover DNA from samples which are too degraded for PCR amplification. In addition, by only studying very short DNA fragments, one should theoretically encounter a lower rate of contaminating exogenous DNA (Figure 5). This is possible because modern DNA tends to have a higher molecular weight than aDNA and comprises a relatively smaller proportion of short DNA strands found in ancient samples. Nevertheless, NGS has drawbacks including expensive instruments and the challenge of analyzing gigabytes of data. Several high-profile publications in vertebrate aDNA have utilized NGS (e.g., Green et al., 2010; Miller et al., 2008), although once again, plant aDNA research lags slightly behind. Based on findings from other NGS studies, it is anticipated that plant aDNA will soon employ NGS for deep cloning, shotgun sequencing, and targeted capture of certain genetic regions.

Deep cloning

Through most of the history of aDNA research, bacterial cloning of PCR amplicons was used as a means to investigate the composition of DNA sources within complex sources of DNA, such as the plant components of coprolites. Unfortunately, however, while useful, the number of cloned PCR products that required sequencing in order to fully characterize a complex substrate was difficult to achieve. Thus, the method rarely was able to describe, for example, the rarest components in a sample. NGS provides an efficient – and reasonably affordable – alternative. Rasmussen et al. (2009) employed NGS deep cloning of plant cpDNA PCR products from ancient human coprolites and recovered 286 sequences. Thus, deep cloning using NGS is a viable alternative to transforming and sequencing hundreds of bacterial colonies. Furthermore, deep cloning can become relatively inexpensive when multiple samples are combined into a single NGS run; the origin of each DNA segment is easily determined using sample-specific DNA index tags which are attached to aDNA molecules (ligated) before samples are merged into a common pool.

Shotgun sequencing

Determining the DNA sequence of large sections of a genome is challenging for people studying aDNA due to the fragmentation of the template molecules. NGS offers a solution to this problem through shotgun sequencing of the fragmented templates. Although randomly chosen from the aDNA extract, the large number of sequences generated in parallel in each sequencing run (hundreds of thousands to tens of millions) means that large amounts of aDNA sequence can, in theory, be rapidly generated. Shotgun sequencing with NGS platforms has already been performed on ancient vertebrate samples, most notably for whole-genome sequencing (WGS) of Neanderthals (Green et al., 2010) and woolly mammoths (Miller et al., 2008). In spite of these advances, the shotgun sequencing of ancient samples is problematic because most recovered sequences are derived from bacteria and fungi – primarily saprotrophs which feed on organic matter *postmortem*. Therefore, it is necessary to shotgun sequence more DNA from ancient samples than modern ones. Nevertheless, plant aDNA researchers can apply NGS

Figure 5 Relationship between DNA fragment length and copy number in ancient samples. Due to DNA degradation, ancient samples contain many short DNA strands but very few long segments. Contamination from modern sources, on the other hand, is expected to be of higher average molecular weight with a relatively random distribution of sequence length. Therefore, regardless of the extent of contamination, it is advantageous to analyze short DNA fragments from ancient samples. By using NGS to study DNA strands 25–35 bp in length, one can efficiently isolate aDNA sequences from the ‘background noise’ of modern contamination. Based on DNA sequences found in 28 000-year-old skeletal remains of a Siberian mammoth (Poinar et al., 2006, Figure S1).

shotgun sequencing for various purposes. For example, WGS of extinct species or agricultural cultivars will undoubtedly reveal lost genes and unknown genetic diversity. Bulk specimen samples, like coprolites and archaeological sediment, can also be shotgun sequenced on NGS platforms in order to recover and identify all taxa contributing to the sample. In other words, it is possible to forgo an amplification of a common genetic marker and directly obtain a picture of the entire biological community represented within a sample. Rates of contamination could be similarly quantified using the relative frequency of DNA sequences that would not be expected to be found in the sample, at least according to well-established paleontological and archaeological knowledge. For example, Rasmussen et al. (2009) recovered fragments of cattle (*Bos taurus*) DNA in a 14 000-year-old Native American coprolite but argue it is a laboratory reagent contaminant because cattle were not present in the Americas before their introduction by Europeans.

Targeted capture

As discussed, shotgun sequencing ancient samples frequently yields a disproportionately low amount of endogenous DNA. New technologies have been developed to target sequences of interest, including primer extension capture (PEC) and

array- and solution-based sequence capture (Knapp and Hofreiter, 2010). PEC uses biotinylated oligonucleotide primers to hybridize with sequences of interest, for example, around an mtDNA genome. Hybridized sequences are isolated through the use of streptavidin-coated magnetic beads, and all other DNA fragments are washed away. In this way, NGS can be efficiently applied to just the regions of interest. This approach has been used on ancient Neanderthal samples to recover the complete mtDNA genomes of five Neanderthals (Briggs et al., 2009). Like PEC, microarrays on glass slides target sequences of interest, but they have the advantage of capturing many more loci. Burbano et al. (2010) used microarrays to investigate ~14 000 single-nucleotide polymorphisms (SNPs) from Neanderthal samples; remarkably, this approach enriched targeted areas by nearly 200 000 times. The first targeted capture experiment on plant aDNA was published by Ávila-Arcos et al. (2011) on a collection of maize cobs and kernels up to 1000 years old. Using a set of RNA ‘baits’ in solution, the authors targeted 670 loci in the chloroplast and nuclear genomes and recovered up to 29 times more DNA of interest than shotgun (random) sequencing. The vast difference in enrichment values between Burbano et al.’s (2010) Neanderthal study and Ávila-Arcos et al.’s (2011)

maize study is partially due to optimization but also reflects different ways of calculating enrichment. Undoubtedly, plant aDNA research has only begun to capitalize on targeted capture methods to investigate genes of interest.

Analysis of Non-DNA Biomolecules

Ancient RNA

Although millennial-scale preservation of plant DNA has been studied for two decades, researchers have recently recognized that RNA can also be preserved at levels that enable informative sequence analysis. Paleogeneticists have so far ignored the transcriptome because RNA's single-stranded structure lacks the chemical stability of double-helical DNA, presumably leading to degradation of RNA shortly after the death of an organism. Contrary to this assumption, various observations have suggested that it is possible for RNA to survive for thousands of years, at least in seeds. Most notably, [Sallon et al. \(2008\)](#) report the successful germination and growth of a ~2000-year-old date (*Phoenix dactylifera*) seed excavated at Masada (Israel). For the seed to have germinated, RNA must have been present in a relatively undamaged state. Research into the preservation of ancient RNA is ongoing, and preliminary findings have been presented at conferences and reported by scientific media ([Callaway, 2010](#)). Future analyses of ancient transcriptomes will provide an important counterpart to aDNA research because RNA plays several special roles in living cells. For example, messenger RNA (mRNA) acts as the intermediary between DNA and protein synthesis. Unlike DNA, many copies of an mRNA molecule can be present in a cell at one time, as required by cellular demands and environmental conditions. Conversely, a gene may be inactive during certain developmental stages and no mRNA molecules are produced. Another form of RNA, microRNA (miRNA) acts as a gene regulator, turning on and off different parts of the genome. This is particularly interesting because it is believed that the bulk of evolutionary change occurs through gene regulation rather than novel mutation (see [Chen and Rajewsky, 2007](#)). Thus, by studying ancient mRNA and miRNA, it will be possible to better understand the evolutionary histories of plants. It should be noted that seeds are perhaps the only organic substrate that preserves RNA because they have evolved specifically to disperse and protect genetic sequences.

Ancient protein

As with ancient RNA, the analysis of proteins preserved in ancient samples can serve as a complement to aDNA research. Because proteins represent an end product of the genome in any specific tissue, they therefore represent an alternative way to investigate ancient organisms. Due to the redundancy of the genetic code – that is, multiple codons code for the same amino acid – closely related species may share identical proteins although their DNA sequences may differ. For this reason, proteins are rarely studied to infer evolutionary relationships. On the other hand, some proteins are better suited to long-term preservation than DNA or RNA. Thus, it may be possible to extract proteins from samples that are too degraded to yield nucleic acids. Analysis of 1400-year-old grape seeds by [Cappellini et al. \(2010\)](#) demonstrates the

advantages of combining the avenues of aDNA and ancient proteins.

Ancient protein resurrection

The reconstruction of extinct proteins may sound like science fiction but is now a reality in cutting-edge genetic research. Rather than extracting proteins from ancient samples, this approach starts with aDNA sequences and builds fresh proteins as specified by the genetic code. This allows scientists to investigate how ancient proteins compare to modern analogs. [Campbell et al. \(2010\)](#) were the first to 'resurrect' ancient proteins with the production of woolly mammoth hemoglobin. The researchers determined the sequence of the mammoth hemoglobin gene, expressed the protein using plasmids, and then discovered unknown adaptations which improve hemoglobin's effectiveness at low temperatures. This approach will be especially important in plant aDNA for understanding how domesticated crops have evolved as they were transported and grown around the world.

Conclusions

Developments over the last 20 years in molecular biology, sample retrieval, and analytical techniques have enabled the field of ancient plant DNA to mature into a position where it can be a valuable asset to Quaternary science. aDNA studies are, however, limited by DNA survival, and researchers must be aware of the serious consequences that this can have on the validity of aDNA results (cf. [Gilbert et al., 2005](#)). Thus, although a potentially powerful tool, future contributions are likely to be limited to samples from relatively young or cold environments, and as such, studies should be designed with these limitations of preservation specifically in mind. This will enable the maximization of potential gains and ensure that ancient plant DNA studies continue to provide unparalleled insights into the past.

Introduction

Burning, or combustion, of biomass is a complex process that rapidly oxidizes fuel, releasing energy in the form of heat, as well as greenhouse gases. The flames, often considered synonymous with fire, constitute the visible part of the reaction (Saito, 2001). The combustion equation for vegetation, estimated using cellulose, is $(C_6H_{10}O_5)_n + (6O_2)_n \rightarrow (6CO_2)_n + (5H_2O)_n + \text{energy}$ (Cofer et al., 1997). In addition to carbon dioxide and water vapor, small amounts of nitrogen, sulfur, halogens, and minerals may also be released during a fire event. In nature, however, the combustion reaction is rarely complete, with incomplete combustion resulting in the production of other products such as carbon monoxide, methane, hydrogen gas, hydrocarbons, soot, and charcoal (Figure 1). During a fire, organic matter may not be equally exposed to the combustion process, resulting in the additional production of charred particles. According to Jones et al. (1997), charcoal refers to any black-colored plant-derived material whose chemical composition and ultrastructure (i.e., the submicroscopic structure at the cellular level) have been significantly altered as a result of heating in a fire, though retaining the recognizable anatomic structure of the parent plant. In contrast, charred particles refer to plant material that has been partially blackened and chemically altered as a result of heating in a fire but without significant alteration of the ultrastructure. In this article, these particles will be collectively referred to as charcoal. All Quaternary studies dealing with charcoal, by quantifying particles or taxonomic identification, are called anthracology. Soil charcoal analysis (pedoanthracology) and the analysis based on archaeological material (archaeoanthracology) are important subdisciplines within anthracology.

From an Earth history perspective, stratigraphic deposits containing fossil charcoal reveal correspondence between the first appearance of terrestrial plants in the Silurian period approximately 420 million years ago and biomass burning (Figure 2; Bowman et al., 2009). Higher resolution charcoal records from the last 80 000 years suggest that the incidence of fire disturbance increases during warmer intervals and decreases during cooler intervals, commensurate with climate-driven changes in biomass (Daniau et al., 2010; Marlon et al., 2009). Other studies show that fire disturbance also responds to temporal changes in moisture and vegetation composition (Brown et al., 2005; Grimm et al., 2011; Hu et al., 2006; Ohlson et al., 2011; Power et al., 2008). Combined, these studies and others clearly reveal that fire is integral to the Earth system (Figure 2), both as part of the global carbon cycle (Ohlson et al., 2009) and as an ecosystem process that has influenced the development, dynamics, and configurations of disparate ecosystems worldwide (Bond et al., 2005; Flannigan et al., 2009; Power et al., 2008).

Fire has also played an important role in human development because it has been used for a variety of purposes, such as lighting, heating, and cooking, throughout all world cultures. More recently, since the end of the last Ice Age, fire activity is known to have changed through time in response to human action. For example, ancient peoples in Eurasia used fire to help clear virgin forests in order to create vast agricultural lands (Odgaard and Rasmussen, 2000; Ruddiman, 2003). Today, fire is heavily managed, with potentially troublesome wildfires actively suppressed when possible (Pyne, 1984). At the same time, prescribed fire is also widely used as a tool in forest management, where it is variously applied in hazard reduction, silviculture, habitat enhancement, range burning, insect and disease control, and conservation–restoration of natural systems (Weber and Taylor, 1992).

Study of Charred Particles

Naturalists in the nineteenth century recognized that charcoal was persistent in the natural environment after observing its occurrence in both soil and sediments. However, it was not until the early mid-twentieth century that charcoal was used as a paleoenvironmental proxy for fire disturbance (Iversen, 1941). Thereafter, the use of charcoal in describing and understanding the functioning of Quaternary environments remained limited until the 1970s. At that point, paleoecologists began developing methods to study different aspects of fire and vegetation history. Since the mid-1990s, charcoal records have been widely used as key indicators of natural fire disturbance (Figure 3). In addition, the records have also been used to examine the historical use of fire by people.

Following the pioneering work of Wright (1974), the measurement of charcoal in Quaternary sediment was mainly developed and applied in North America during the early 1970s. Wright contended that past fire could potentially be identified as a key ecological factor influencing both ecosystem changes, through vegetation and soil dynamics, as well as biogeochemical cycling. However, the main development of sedimentary charcoal studies occurred during the late 1980s and early 1990s under the leadership of Clark (1988a,b, 1990), who, as a former student of Wright, developed and advanced specific concepts and methodologies to reconstruct fire history, including continuous high-resolution charcoal studies.

Since then, the reconstruction approach has been further refined through the introduction of quantitative methodologies (Gavin et al., 2006; Higuera et al., 2010; Long et al., 1998), coupled with development of software specifically designed to analyze charcoal records, including both Charster and K1D developed by D.G. Gavin, University of Oregon, and

Figure 1 Charcoal fragments extracted from a sediment core that was collected from Scum Lake, British Columbia, Canada. In general, fragments are classified as charcoal if they are black, opaque with submetallic luster, and exhibit cellular structure (Sander and Gee, 1990). Photographs by K. Brown and N. Hebda.

CharAnalysis (Higuera et al., 2010). Another important advance relates to the development of the Global Charcoal Database (GCD; Power et al., 2008), which has been used to generate regional to global fire disturbance syntheses that have improved our collective understanding of the drivers of fire disturbance.

Longer Term Perspectives

In recent years, the public has become increasingly aware of forest fires, largely due to the fact that there has been an overall global increase in the frequency and magnitude of fire combined with the expansion of human settlements into fire-prone environments. Future changes in fire activity induced by climate (Flannigan et al., 2009) will likely further exacerbate public concern about increasing wildfire along the urban-wildland interface. The overall increase in global fire disturbance during the last two decades may be related to several processes, including increased fuel loads associated with decades of fire suppression as well as changing climate (Gavin et al., 2007; IPCC, 2007; Pitman et al., 2007). Indeed, the general interaction between climate, vegetation, and fire is known to be complex and multifaceted, although climatic factors are considered to be the predominant controls regulating the fire regime (Marlon et al., 2009; Power et al., 2008; Swetnam and Betancourt, 1998). However, vegetation is another important factor that regulates fire by controlling the configuration and flammability of fuels (Bond and Keeley, 2005; Brown et al., 2005; Hu et al., 2006) and by altering local microclimatic conditions (Ohlson et al., 2011). In turn, fire is capable of modifying both climate and the surrounding vegetation. The climate system can be influenced by fire through the emission of greenhouse gases and carbonaceous aerosols (Scholes and Andreae, 2000), whereas forest configuration may be mediated by altering species turnover rates or by selecting for fire-adapted species (Gavin et al., 2007; Overpeck et al., 1990).

Given that recent land management practices have dramatically altered natural fire regimes in many parts of the world,

long-term records provide a context for understanding modern fire regimes (Gavin et al., 2007). To understand the full importance of the factors and processes that regulate fire regimes, scientists, forest managers, policymakers, and other officials need greater insight into the long-term dynamics and variability of fire. There are several approaches through which longer term perspectives can be obtained, including assessment of historical records, fire-scarred tree rings, stand age distributions, and charcoal records. In general, the former approaches provide insight into fire disturbance at subannual to centennial scales, whereas charcoal records can provide subdecadal to millennial perspectives. Clearly, one advantage of charcoal records is that they do not attenuate through time as do tree ring records. Charcoal records may be obtained from lake sediment sequences, peat deposits, small hollows, alluvial deposits, and soils, as well as from archaeological sites where they provide insight into human use of fire.

Stratigraphic Charcoal Records

Through a variety of transport mechanisms and taphonomic processes including convective dispersal as well as postfire wind transport, overland flow, and sediment focusing (Clark, 1988a; Higuera et al., 2007), charcoal particles may enter nearby depositional environments such as lakes or wetlands, where they preserve (Figure 4). With time, charcoal from subsequent fires accumulates within these various environments, eventually forming long-term records of disturbance history. Often, small deep lakes with no inflowing streams or surrounding peatlands are selected as the best sites for Quaternary fire studies because they permit local fire history reconstruction and reduce the amount of ambiguity associated with charcoal source areas from larger basins or those with inflowing streams, which can deliver additional charcoal from the watershed. Records of past fire activity can be recovered using a variety of sampling approaches that are designed to collect continuous sediment sequences (Figure 4). Several different samplers are suitable for the recovery of sediment, with perhaps the Livingstone piston corer (Wright, 1967) being the most well known. The stratigraphic records are typically logged or photographed prior to additional sampling, which often involves extracting known volumes of sediment in contiguous samples, ideally in increments of 1 cm or less. Clark (1988a) and Higuera et al. (2007) indicate that the optimal sampling interval for detecting individual fires should be <0.2 and <0.12 times the mean fire return interval, respectively.

Historically, several techniques have been used to estimate charcoal quantity (Rhodes, 1998), including pollen slide, thin-section, and sieving estimates. In the pollen slide approach, a sediment sample is processed for pollen analysis, which involves chemical digestion (see Pollen Analysis, Principles). The resulting residue is mounted on a glass slide, protected with a cover slip, and examined using a compound light microscope at 400–1000 $\times$ magnification. In addition to pollen, small charcoal fragments will often survive the processing and be found on the slide, and these fragments can be tallied as particles or areas. In general, fragments on pollen slides can be classified as charcoal if they are black, opaque, and tabular or angular in shape (Rhodes, 1998). Wood anatomical structure is generally

Figure 2 Temporal schematic of global fire activity derived using stratigraphic charcoal deposits relative to other aspects of earth history, including evolution of the atmosphere, climate system, and vegetation. The evolution of the genus *Homo* and subsequent human-related fire activities are likewise illustrated. Note that the time scale is logarithmic. difficult to discern in pollen slide charcoal since the light source is from below the sample. The pollen slide approach is attractive because it combines the tabulation of pollen with that of charcoal. A disadvantage of the approach is that charcoal fragments may be chemically or physically degraded during preparation. Another methodological challenge relates to charcoal identification, whereby the definitive classification of a fragment as charcoal can be difficult, given the general small size of the fragments coupled with the persistence of other dark organic material on the slides. In the petrographic thin-section approach, the recovered sedimentary archive is dehydrated under a vacuum, impregnated with epoxy resin, cured, and sectioned (Clark, 1988b). This technique, however, is generally considered both time-consuming and expensive and has not been widely adopted. In contrast, the sieving approach is both simple and relatively quick. Initially, sediment samples are soaked in a deflocculating agent such as 5–10% sodium metaphosphate solution, followed

by gentle sieving through a mesh. The diameter of the mesh openings may vary, although 125–180- μ m mesh diameters are commonly used. The residue caught on the sieve is suspended in water in a gridded Petri dish and examined using a stereomicroscope at 20–40 $\times$ magnification (Figure 4). Charcoal identification can be made using the same criteria as in the pollen slide samples, though in this case, anatomical structure is readily visible and the fragments are often lustrous. Both particle counts and area determinations can be made. Regarding the latter, areas can be estimated using an eyepiece graticule or measured more precisely using specialized imaging software (Lynch et al., 2002). Empirical studies have shown a strong correlation between count and area measures of charcoal abundance (Figure 5; Ali et al., 2009). In addition to providing an estimate of charcoal quantity, another advantage of the sieving approach is that other plant macrofossils present in the Petri dish can be simultaneously tabulated.

Figure 5 Correlation between charcoal fragment and area concentrations in lake sediments. (a) Data from Lac Pas-de-Fond, Quebec ($N=354$); (b) data from Lake Raigejeppe pond, Sweden ($N=245$); (c) data from Lake Klotärnen, Sweden ($N=322$); (d) data from Sarup Sø, Denmark ($N=605$). Although charcoal concentration, expressed in area, volume, or mass, is linked to burned biomass, fragment numbers are not because they undergo breakage during transportation and deposition in nature or during sieving at the laboratory. However, the two descriptors (number and area) are positively correlated. Panels (a) and (b) are reproduced from Carcaillet C (2007) Charred particle analysis. In: Elias SA (ed.) *Encyclopedia of Quaternary Science*, pp. 1582–1593. Amsterdam: Elsevier. The data used in panels (c) and (d) were provided by K. Brown.

From a source area perspective, charcoal recorded from pollen slides is considered a proxy for both local and regional burning. Given its small size (usually $<150\ \mu\text{m}$), pollen slide charcoal is often referred to as microcharcoal (Mooney and Tinner, 2011). Charcoal in this size range is capable of being convected long distances (1–100 km; Clark, 1988a; Peters and Higuera, 2007). In contrast, charcoal isolated with the sieving approach is often referred to as macrocharcoal. Because the fragments are larger (typically $>125\ \mu\text{m}$), the transport distances are generally shorter. Thus, macrocharcoal serves as a proxy for stand- to local-scale fire disturbance where local reflects fires within about 1 km of the basin (Gavin et al., 2003; Higuera et al., 2007). Initial measurements from prescribed burn experiments suggest that most macroscopic charcoal is deposited near the burn edge (Figure 6; Clark et al., 1998; Lynch et al., 2004; Ohlson and Tryterud, 2000). More recent observations from wildland fires (Pisaric, 2002; Tinner et al., 2006), coupled with the development of a particle distribution model (Higuera et al., 2007; Peters and Higuera, 2007), show that macrocharcoal fragments have a potential to be transported several to tens of kilometers from source (Figure 6). Critically, however, this increased transport distance does not preclude identification of local fires though peak charcoal detection in lake sediment records.

In addition to these two approaches, several other sediment-based fire reconstruction approaches are being developed. Though relatively nascent in paleofire reconstruction, chemical groups such as monosaccharide anhydrides, light carboxylic acids, polycyclic aromatic hydrocarbons, and lignin burning products have potential to serve as proxies for past fire. Within the monosaccharide anhydride group, Holocene records of biomass burning have been developed using the

molecular marker levoglucosan (Elias et al., 2001). Levoglucosan is a monosaccharide derivative formed from the thermal breakdown of cellulose during combustion, and its concentration can be measured in any residue of fuel that contained cellulose (Louchouart et al., 2009). It is produced in large quantities, transported in smoke plumes, and deposited by both wet and dry deposition mechanisms (Kerhwalid et al., 2010). Another interesting application in charcoal research uses reflected light microscopy to estimate the temperature of charcoal formation (McParland et al., 2007). This method has implications for both understanding combustion temperatures of natural wildfires and for understanding the human use of wood and charcoal as a fuel source.

Analysis of Sediment Charcoal Records

Given that the sieved charcoal method now constitutes the most widely used and recommended approach in paleofire reconstruction, the method will be examined in greater detail (Figure 7; Higuera et al., 2010). Following sieving and quantification, the estimates of charcoal are expressed as concentrations (Figure 8), either as counts (fragments cm^{-3}) or areas ($\text{mm}^2\text{cm}^{-3}$). The charcoal accumulation rate (particles $\text{cm}^{-2}\text{year}^{-1}$ or $\text{mm}^2\text{cm}^{-2}\text{year}^{-1}$; CHAR), alternatively referred to as charcoal flux, is determined by multiplying the charcoal concentration by vertical accretion rate (cm year^{-1}), where the latter rate is usually determined with the aid of an age-depth model that is derived using radiometric dating of selected samples and any other available chronological indicators. CHAR is often the preferred metric because it accounts for changes in accretion rate through time that can either

Figure 6 Pattern of charcoal accumulation rates with distance from burned forests. (a) The International Crown Fire Modeling Experiment was performed in *Picea mariana* (black spruce) forest, Northwest Territories, Canada, and (b) the Bor Island experiment fire in *Pinus sylvestris* (Scots pine) forest, Siberia. Charcoal accumulation declines rapidly with distance from the burn edge, with most charcoal deposited within 60 m of the burned edge (reproduced from Lynch JA, Clark JS, and Stocks BJ (2004) Charcoal production, dispersal, and deposition from the Fort Province experimental fire: Interpreting fire regimes from charcoal records in boreal forests. *Canadian Journal of Forest Research* 34: 1642–1656). Particle dispersal model output showing cumulative charcoal deposition in a lake with increasing distance for (c) 10 m and (d) 1000 m modal injection height scenarios. Reproduced from Peters ME and Higuera PE (2007) Quantifying the source area of macroscopic charcoal with a particle dispersal model. *Quaternary Research* 67: 304–310.

concentrate or dilute the quantity of charcoal particles, enabling sample-to-sample comparison. CHAR samples are typically interpolated to a constant temporal resolution to accommodate uneven sampling intervals caused by downcore variations in accretion rate. The interpolated CHAR record consists of discrete peaks that are superimposed on a slowly varying mean (Higuera et al., 2010), with the former reflecting the peaks component and the latter the background.

Interpolated CHAR records can then be decomposed into both background and peaks components (Figures 7 and 8). The background component reflects the low-frequency portion of the CHAR series that varies slowly through time in response to changes in charcoal production and transport, as well as sediment mixing and sampling. It can be modeled using a curve fitting algorithm (Briles et al., 2008; Higuera et al., 2010). Removal of the background component from the CHAR series, either through subtraction (residual) or division (ratio), results in the detection of the high-frequency peak component. The peak component is comprised of both fire-induced signal and non-fire-related noise, with the latter related to distant fires, analytical noise, and charcoal redeposition (Hallett and Anderson, 2010). Consequently, a threshold can be applied to the peak component in order to separate signal from noise. A Gaussian mixture model (Gavin et al., 2006) can be used to identify the noise, with a specified percentile value (i.e., the 99th percentile) of the peak component

distribution used as a separation threshold that distinguishes signal from noise. In rare instances when background charcoal does not vary through the record, a global threshold can be determined using the peak distribution from the entire record. Alternatively, local thresholds, robust to changes in background charcoal, peak variance, and the detrending model, can likewise be generated for each sample in a record by sampling the peak distribution within a moving window (Higuera et al., 2010). Peaks that are identified as being derived from local fires are referred to as fire episodes because they cannot unambiguously be related to a single event and may owe their origin to more than one fire that burned near the basin. Importantly, a minimum count test can be used to evaluate whether the peaks identified result from a statistically insignificant change in charcoal, and if so, then the peak can be rejected. The time difference between peaks reflects the fire return interval. Estimates of fire frequency can be obtained by summing the peak series over a specified window width and smoothing. In addition to this technique, other approaches can be used to estimate temporal trends in fire frequency. For example, Clark et al. (2002) and Brown et al. (2005) used Fourier power spectral analysis and wavelets to examine frequencies and periodicities in grassland charcoal records.

Critically, CHAR can vary greatly from location to location because each study site possesses a unique set of characteristics related to the size and type of basin, physiography of the

Figure 7 Flow diagram showing the steps and choices required during charcoal decomposition. Reproduced from Higuera PE, Gavin DG, Bartlein PJ, and Hallett DJ (2010) Peak detection in sediment-charcoal records: Impacts of alternative data analysis methods on fire history interpretations. *International Journal of Wildland Fire* 19: 996–1014. Copyright © International Association of Wildland Fire (USA) 2010.

catchment area, accretion rates, vegetation types, landscape structure, and fire regime. Because of this inherent spatial variability, single records yield site-specific reconstructions sensitive to watershed-scale processes, whereas collated records that combine multiple fire history reconstructions allow for larger spatial syntheses and insights into the regional climate controls of fire (Carcaillet and Richard, 2000; Power et al., 2008).

Soil Charcoal

In a forest fire, much of the charcoal produced falls within the burned area (Ohlson and Tryterud, 2000) and is gradually incorporated into the soil by bioturbation (Carcaillet, 2001). In addition to mixing by biological activities, climatic processes and tree uprooting by windthrow can mix soil, contributing to a general lack of stratification. Consequently, soil charcoal is of limited use for Quaternary reconstruction because of compromised stratigraphic integrity, though the age of single charcoal fragments can be measured by accelerator mass spectrometry (AMS) dating to establish time of fire, with consideration given to the inbuilt age of the wood (Gavin et al., 2003). From a methodological perspective, analysis of soil charcoal involves the collection and sampling of soil profiles, with charcoal

separated from other soil particles by flotation or sieving and examined using a stereomicroscope. If taxonomic identification is desired, individual charcoal fragments can be compared to descriptions from specialized literature (e.g., Neumann et al., 2001) or regionally explicit reference collections.

Soil charcoal archives have several unique applications. For example, they provide records from areas where depositional basins may be rare (Hopkins et al., 1993) and can be used to examine general changes in forest composition and fire disturbance at the landscape scale (Ohlson et al., 2011). In addition, they are also useful in determining the past position of treeline (Carneli et al., 2004). Soil charcoal records can also be used to examine the spatial variability of fire resulting from landscape structure and human activity (Gavin et al., 2003). For instance, it has been observed that on the west coast of Vancouver Island, Canada, topography is an important factor affecting the distribution of fire disturbance, with south-facing slopes exhibiting a greater incidence of fire compared to north-facing slopes. Gavin (2003) also used soil charcoal records to examine trends in soil disturbance, which are typically too long to measure using plot-based studies and thus are poorly understood. Finally, by measuring the carbon concentration in soil charcoal, it is possible to report on soil charcoal carbon pools (Ohlson et al., 2009), which are important for determining carbon budgets (Table 1).

Figure 8 Decomposition of a 3000-year-long sedimentary charcoal record from Foy Lake, Montana, USA. Charcoal counts (red) were converted to charcoal accumulation rates ($\text{CHAR} = \text{particles cm}^{-2} \text{year}^{-1}$) (magenta) by multiplying the charcoal concentration by accretion rate (blue). CHAR values were interpolated to 5-year intervals and smoothed using a 500-year window width (background). Fire episodes are indicated by a vertical (red) symbol when CHAR exceeds background by calculating residuals and using a locally defined threshold and Gaussian mixture model. Peak magnitude illustrates the size of the charcoal peak above background, and the smoothed fire return interval (green) illustrates the years per fire. The bottom panel shows smoothed fire frequency using a 1000-year window to illustrate the change in peak frequency through time. The data used in this figure were provided by M. Power.

Table 1 Range of soil charcoal quantities in various vegetation types and locations

<i>Vegetation type and location</i>	<i>Quantity (kg charcoal ha⁻¹)</i>	<i>Reference</i>
Deciduous forest (Canada)	350–1300	Bélanger et al. (2004)
Boreal forest (Sweden)	1000–2100	Zackrisson et al. (1996)
Boreal forest (Norway and Sweden)	0–2200	Ohlson et al. (2009)
Alpine grassland (France)	0–200	Carcaillet and Talon (2001)
Sub-Alpine forest (France)	5–20 000	Carcaillet and Talon (2001)
Mediterranean forest (France)	8500–100 000	Carcaillet et al. (1997)
Savanna (Africa)	150	Carcaillet and Talon (2001)

Archaeological Charcoal

Charcoal from archaeological sites can be used to reconstruct past environments and ascertain how prehistoric populations may have used or exploited fire (Heinz and Thiébault, 1998; February, 2000; see [Archaeological Applications](#)). Charcoal sampled in archaeological sites largely results from the charring of wood used as fuel, building material, or material for the manufacture of domestic implements. Furthermore, the burning of dwellings can often be associated with site abandonment, yielding large amounts of other archaeological charred material such as seeds and bones. This material provides additional information about the precise use of wood by distinct human populations or societies. Consequently, archaeological charcoal can be used to examine past lifeways and the relationship that humans have had with their environment (Chabal, 1997). Laboratory methods for analyzing archaeological charcoal are similar to those used in pedoanthracology, although the size of identified fragments is generally larger in archaeology (>2mm).

As an example, analysis of charcoal composition and tree ring structure from Mesolithic (early Holocene) cooking pits in northern Sweden reveals that large pieces of pine (*Pinus*) wood were often selected as fuel, even though other types of vegetation were available (Carcaillet, 2007). Critically, this restrictive charcoal assemblage pattern suggests that Mesolithic hunters preferred pine as fuel, likely because it was abundant in the environment and well suited for combustion. In another European example, archaeological charcoal was used to infer the type of fuel selected for charcoal production in charcoal kiln soils (Ludemann and Nelle, 2002). In certain regions of Europe, charcoal kilns abound, demonstrating the importance of charcoal production in the recent past where it was used in industrial activities such as glass making. Charcoal is lighter than wood but with the same calorific benefit, so the production of charcoal saved both energy and effort because the transportation of wood from forest to town was avoided.

In North America, lacustrine and archaeological records have both been used to examine Aboriginal and European burning practices (Clark and Royall, 1996; Turner, 1991), which vary spatially. For example, in coastal western Canada, archaeological findings suggest that large sophisticated Aboriginal populations with permanent settlements developed during the last 2000 years (Brown and Hebda, 2002; Hebda and Mathewes, 1984) and used fire both domestically and as a landscape management tool. Thereafter, a switch from Aboriginal burning to European forest clearing and

utilization is shown by a marked change in charcoal deposition across the pre- to post-European settlement transition (McDadi and Hebda, 2008). In another example from Central America, archaeological and paleoecological research suggests significant areas of Neotropical forests were cleared and burned to facilitate agricultural activities before the arrival of Europeans (Dull et al., 2010). Recent synthesis has established that a major reduction in biomass burning occurred ~500–600 years ago, as a result of both climatic (Little Ice Age) and anthropogenic forcing (pandemics; Power et al., in press; Ruddiman, 2003; Ruddiman et al., 2011). As more archaeological and paleoclimate information become available for the region, the drivers of changing charcoal abundance in the Neotropics will become clearer.

Global Charcoal Database

The Global Charcoal Database (GCD) is an emerging tool for mapping and characterizing changing fire regimes on regional to global scales through time (Power et al., 2009). The database is unrestricted and publically accessible (see [‘Relevant Websites’](#)). In total, 405 sedimentary charcoal records, spanning over 200 000 years of Earth history are featured in the GCD (Figure 9). The primary function of the database is to serve as a tool for testing hypotheses about the changing drivers of fire regime on centennial to millennial timescales (see [Databases and Their Application](#)). Within the database, charcoal quantities, sample volumes, depths, and modeled ages are included, along with appropriate metadata for parsing individual sites based on unique characters such as vegetation type or size of watershed. The radiometric dating approaches (AMS or conventional dating), measured ages, and calibrated ages for all age models are likewise included. The creation of the database also represents the first step in providing the necessary empirical data to test the validity of vegetation and fire models that simulate past and future ecosystems under markedly different biological and physical conditions from present. Currently, the GCD is being used to produce regional and global syntheses that examine the linkages between Quaternary climate variability and biomass burning (Marlon et al., 2009; Mooney et al., 2011; Power et al., 2008; Vannière et al., 2011).

To facilitate syntheses using GCD data, a standardization approach needs to be used (Figure 10) that normalizes individual records and stabilizes the variance so that charcoal data can be compared from hundreds of sites that employ a wide range of sampling, processing, and quantification techniques

Figure 9 Locations of available records in the Global Charcoal Database (red dots) relative to the distribution of global biomes (World Wildlife Federation).

(Power et al., 2008, 2009). Composite records for regional analysis are created by smoothing standardized charcoal time series (Marlon et al., 2009). Individual records are first sampled and smoothed (Cleveland and Devlin, 1988). Once the individual records have been smoothed, a three-step standardization protocol is used to facilitate comparisons between sites and through time. The standardization procedure involves rescaling values using a minimax transformation, homogenizing the variance using a Box-Cox transformation (Figure 10) and rescaling values once more to Z-scores using an appropriate base period (e.g., the last 2000 years) to achieve a common mean and variance. Using this methodology, several papers have highlighted key findings in regional biomass burning that demonstrate strong linkages between fire and past climate (e.g., Marlon et al., 2009; Mooney et al., 2011; Power et al., in press; Vannière et al., 2011).

There are relatively few global charcoal records available for documenting the Last Glacial Maximum (LGM), but the number of sites doubles for the interval spanning the last 10 000 calendar years before present (cal BP). These data, when standardized and combined, document broad-scale changes in charcoal accumulation through time and are interpreted as reflecting regional changes in biomass burning. The dominant patterns of biomass burning have been discussed in Power et al. (2008) and Marlon et al. (2009) for broad geographic regions, within the context of millennial-to-centennial scale trends in fire and climate. These studies have concluded that climate forcing, both directly and indirectly, has had a major impact on global biomass burning since glacial times. The most important factors influencing regional climate and biomass burning since the LGM are (1) the seasonal and latitudinal distribution of insolation, (2) disappearance of the Northern Hemisphere ice sheets, (3) changes in paleogeography related to isostatic rebound and rising sea levels affecting the degree of continentality, (4) changes to ice caps in the

tropics and Southern Hemisphere, (5) changes in global sea surface temperatures, and (6) changes in atmospheric composition. These aspects of the global climate system have been directly and/or indirectly linked to changes in regional fire activity through regional-scale atmospheric circulation anomalies and concomitant changes to the incidence of fire-supporting climate regimes.

Reconstructions of global biomass burning since the LGM suggest that overall fire disturbance was generally low during the LGM and remained low during the glacial and late-glacial interval from 21 000 to ca. 14 000 cal BP (Power et al., 2008). At this time, global climate was colder and drier, atmospheric CO₂ levels lower, and terrestrial biomass significantly reduced relative to present. Given the cool, dry nature of the troposphere, both convection and lightning activity would have been limited. This factor, combined with the noted general reduction of fuel load, may have contributed to the prolonged period of low global fire activity. As Northern Hemisphere ice sheets waned and atmospheric CO₂ concentrations increased, terrestrial vegetation expanded across the high latitudes, and global fire activity generally increased over the last ~10 000 years, with an exception during the last two millennia. For example, in the early Holocene, sea surface and terrestrial temperatures increased in the Northern Hemisphere in response to changes in insolation. At the same time, vegetation cover expanded, and fire became an increasingly dominant process within the Earth system. However, global biomass burning has declined during the last two millennia. Embedded within that long-term trend are centennial-scale increases and decreases in fire associated with temperature variability such as the Medieval Climate Anomaly (Stine, 1994) and Little Ice Age, respectively. The most obvious human impacts on global fire regimes have occurred since the Industrial Revolution, with dramatic increases in fire activity after AD ~1750 because of land clearance and decreases after AD ~1850 as a result of forest management (Marlon et al., 2012).

Figure 10 A comparison of (a) original and (b) transformed flux data (particles cm⁻² year⁻¹) from Foy Lake, Montana (Power et al., 2011), demonstrating the impact of the Box-Cox transformation. Comparing the distribution of the (c) original and (d) transformed data as frequency distributions illustrates how the optimal value of λ (e.g., 0.0311 in this example) normalized the distribution of the data. (e) A 13000-year regional composite that was created from 26 transformed charcoal records from the northern Rocky Mountains, expressed as Z-scores of charcoal anomalies. In this case, the entire records were used to calculate the base period for the Z-scores. All charcoal samples were first transformed and then smoothed using a 500-year window (red line). The dark gray line illustrates a 100-year smoothing window, and the upper and lower 95% confidence intervals are shown in light gray. (f) The numbers of records contributing to the 500-year smoothed time series. (g) Locations of the charcoal records used in the composite. The data used in this figure were provided by M. Power.

Future Directions

Although significant progress has been made in recent decades regarding use of charcoal in Quaternary studies, much work remains. From a spatial perspective, the GCD reveals significant gaps in the distribution of charcoal records (Figure 9). Increased sampling is required in regions that are currently underrepresented, including Russia, eastern Europe, middle Asia, and Africa. Furthermore, it would be desirable, though perhaps not practical, to resample and analyze some previously published records that are poorly resolved. From a methodological perspective, recovered sedimentary sequences should ideally be sampled contiguously and at high resolution. The recent advances in the decomposition of charcoal time series for fire return interval and frequency estimates have resulted in a surge of research (Figure 3). However, detailed

understanding of the peak magnitude component remains elusive and needs to be investigated further. This will require additional calibration studies that relate peak magnitudes to burn areas, fire intensities, and charcoal delivery. Furthermore, many of the recent methodological advances were developed using charcoal records from conifer-dominated ecosystems that often experience infrequent, stand-replacing fires. An evaluation of these advances is now required using data from different vegetation types to assess the universality of the methods across ecosystems. For example, in fires in Mediterranean ecosystems, the wood is often mineralized from high combustion temperature as a result of volatile compounds such as terpenes and low residual humidity in the vegetation. Consequently, wood charcoal production tends to be low, whereas ash production may be high relative to boreal and temperate regions. In addition, other methods of fire

reconstruction such as molecular and reflected light microscopy approaches should be further developed and evaluated. Finally, more data model comparisons are needed, with a view towards improving our understanding of the mechanisms that cause fire regime shifts (Brubaker et al., 2009).

Reconstructing and modeling carbon flux and storage at landscape and global scales should be further explored using charcoal databases. However, certain parameters need to be highlighted, such as the rate of carbon emission during fire, with consideration given to different vegetation types. Notably, sedimentary and soil charcoal records provide a means for evaluating the historical role of fire in sequestering refractory carbon and should be used to measure charcoal carbon pools. Given the long-term nature of the sedimentary records, they could also be used in studies that focus on the recalcitrant nature of charcoal.

Paleofire reconstructions using the GCD provide an additional opportunity for hypothesis testing and validation of paleofire simulations that attempt to capture the linkages among climate, vegetation, and fire. Accurately simulating past patterns and mechanisms of global and regional fire activity is a critical step toward assessing whether future changes in climate and fire can be realistically projected. Simulations that capture the spatial and temporal patterns of future fire regimes will help landscape managers prepare for the affects of climate change and help governmental agencies decide on how best to manage and allocate fire-related resources. The GCD is one of the many new tools available for fire scientists to deepen our understanding of fire in the Earth system, and it should be further developed through increased data contributions, leading to the production of additional informative analyses.

Conclusions

Quaternary investigations using charcoal as a proxy or measure continue to increase (Figure 3). These investigations are not discipline-specific but rather cross-disciplinary and include paleoecology, fire ecology, and archaeology, and also soil, carbon, and climate studies. Within the last decade, advances in the numerical treatment of charcoal time series and the development of a GCD have resulted in improved characterization of past fire regimes and the drivers of fire regime change. Future studies should focus on the continued improvement and testing of quantitative methods, advancement of new reconstruction approaches, data model comparisons, and issues related to human use of fire, carbon cycling, and sampling of under-represented regions.

Introduction

Phytogeography is the study of the distribution of plants or taxonomic groups of plants and its focus is to explain the ranges of plants in terms of their origin, dispersal, and evolution (Matthews et al., 2003). As the minimum time period needed to observe changes in abundance and distribution of plants most often is longer than the career or life span of a geographer, paleoecological data and their understanding are of great importance. The phytogeography of the fossil record is, according to Wnuk and Pfefferkorn (1996), just as important as understanding modern phytogeography. The role of climate change in changing the distribution of species is the core area of biogeographical research (MacDonald et al., 2008).

The need for observations on longer timescales is acute because most species distributions are not in equilibrium with present climate and changes are occurring at larger scales. Historical processes, such as dispersal and colonization since the last glacial stage, and time are important for explaining and understanding changes in the distribution of species, vegetation belts or biotas, and ranges and patterns of population responses to environmental change (e.g., Bhagwat and Willis, 2008; Birks, 1989; Cruzan and Templeton, 2000; Grytnes et al., 1999; Huntley and Webb, 1989). Pollen and plant macrofossil data from different sedimentary records are well suited, and the construction of databases such as the European Pollen Database (Fyfe et al., 2009) and the Neotoma database (see [Databases and Their Application](#)) has facilitated the compilation of data on larger temporal and spatial scales as well as testing hypotheses (Binney et al., 2009; Cruzan and Templeton, 2000; Gajewski, 2008). For large-scale studies or biome-scale studies, pollen data can be aggregated to a higher taxonomic level, thus avoiding the problem in pollen analysis with low-resolution taxonomy (Gajewski, 2008). Additionally, there are an increasing number of sites where pollen and macrofossil analyses have been done at high temporal resolution and where more details can be studied. These may show that equilibrium states are never reached, but vegetation is under continuous change in a dynamic world.

Climate (temperature, precipitation) is believed to be one of the main forcing factors for plant distributions, but there are also other possible contributing factors or types of environmental change that affect ecosystems, such as fires, in addition to human impact, competition, succession, and invasions (McLachlan and Clark, 2004). These factors might covary spatially, so it is sometimes difficult to separate the direct importance of one specific factor (Grytnes et al., 1999).

According to MacDonald et al. (2008), it is important to understand climate change and its potential impact on species, populations, and communities. Because future climate changes are expected to take place at a greater rate than those in the recent geological past (Overpeck, 1996), it is extremely

important to use insights from paleoecology and paleophytogeography to be able to fully understand present-day and possible future biotic responses to environmental change.

Impact of Ice Ages

Ice Ages have had significant impacts on the geography of global biotas (Willis et al., 2004). The changes between cold and warm climates have led to repeated restriction and isolation of many populations, which has driven the formation of new species. Evidence for this can be found in the fossil pollen and plant macrofossil records. Repeated glacial–interglacial cycles have occurred throughout Earth's history on Milankovich timescales (400, 100, 40, and 23–19 ka). The most recent and the best studied periods are the Quaternary Ice Ages covering the last 2.6 million years (My) (Hooghiemstra and Van der Hammen, 2004; Willis et al., 2004). According to Frogley et al. (1999), up to 80% of Quaternary time has been characterized by glacial conditions, while only 20% of the time had conditions similar to or warmer than the present.

During the Quaternary Ice Ages, dramatic environmental changes led to major shifts in the distribution and abundance of vegetation and vegetation belts (Bennett, 2004; Hooghiemstra and Van der Hammen, 2004). The main response of vegetation has been changes from forest to non-forested vegetation when climates have been colder (Tzedakis et al., 1997). Willis and Niklas (2004) found little evidence for increases in plant diversity during the Quaternary but concluded that stasis and extinction were the main responses to loss and fragmentation of habitats. More recent work has shown that the Quaternary Ice Ages have been essential for genetic diversification and speciation. According to Willis and Niklas (2004), three evolutionary scenarios can explain the fragmentation and re-expansion of species ranges during the Quaternary: (1) species persistence, (2) extinction, and (3) classical allopatric speciation due to geographical isolation. Some species were restricted to isolated glacial refugia, whereas other species persisted in large populations. There is no evidence of increased speciation during the Quaternary period, and local extinctions (extirpations) were more the case than total extinctions (Willis and Niklas, 2004). One of the few examples of plant species extinction is that of *Picea critchfieldii* in eastern North America in the Late Quaternary (Jackson and Weng, 1999). In the Colombian Andes, pollen records show that the treeless paramo vegetation was more widespread during Pleistocene glacial intervals, whereas during interglacial times, it was limited to the higher altitudes, as the upper tree limit advanced upslope (Hooghiemstra and Van der Hammen, 2004). Similar patterns have been noted in many other mountainous regions (e.g., the western United States).

The Quaternary Ice Ages also had an impact on the genetic diversity within species. [Petit et al. \(2003\)](#) examined the distribution of variation in neutral chloroplast DNA markers throughout the ranges of 22 common tree species in Europe. They found that genetic diversity was highly differentiated in southern populations, consistent with the expected effect of population isolation during the glacial intervals. The highest genetic diversity level was found at mid-latitudes where lineages mixed during the Holocene recolonization, giving the northern populations a small subset of genetic diversity generated in glacial refuges ([Petit et al., 2003](#)).

The Last Glacial Phase

A major problem arising from glaciation is the effect of glaciers and ice sheets overriding the land surface and removing much of the surficial sediment, making the included fossils as well as the number of suitable sites scarce. Reconstruction of Late Glacial Maximum (LGM) (ca. 21 ka BP) ranges of plants is important for assessing climate and biotic sensitivity to various forcings, because orbital parameters were similar to today, but the boundary conditions and forcing factors were different from today during the LGM ([Jackson et al., 2000](#)). In North America and Europe, LGM sites are few, many do not yield good dates, and the derived paleobotanical records lack modern analogs in both climate and vegetation ([Jackson et al., 2000](#); [McLachlan and Clark, 2004](#)). This has led paleoecologists to infer vegetation on broader scales using biomes and plant functional types.

In Europe, temperate trees and woodland species must have survived in smaller refugia, whereas in North America, the vegetation migrated to more restricted zones or larger areas in the south. According to [Stewart and Lister \(2001\)](#), treeless vegetation dominated the unglaciated parts of northern Europe, Asia, and northern America during the last glacial interval. It has for long been the only view based on pollen data that woody taxa in Europe survived in three refugia during the LGM: on the Iberian Peninsula, in Italy, and in the Balkans ([Bennett et al., 1991](#); [Huntley and Birks, 1983](#); [Willis, 1994](#)). The position of these has been debated in recent decades. Pollen alone is often not sufficient to indicate the presence of species, due to its long distance transport and poor taxonomic resolution ([Jackson et al., 2000](#)). Therefore, it has been difficult to detect these small, isolated populations by pollen only ([Birks, 1989](#)). It has been demonstrated by [Loehle \(2007\)](#) that pollen production is reduced in cold environments in combination with low concentrations of atmospheric carbon dioxide. One approach for tracing these small refugial populations is to examine other proxies, such as plant macrofossils ([Bhagwat and Willis, 2008](#); [Birks and Birks, 2003](#)) and genetic data ([McLachlan et al., 2005](#); [Qiu et al., 2011](#)).

New macrofossil data and genetic studies indicate that cold-adapted taxa survived further north during the full glacial ([Bhagwat and Willis, 2008](#); [Binney et al., 2009](#); [Birks and Willis, 2008](#); [Väliranta et al., 2011](#); [Willis and van Andel, 2004](#)). For Beringia, [Brubaker et al. \(2005\)](#) conclude that small populations of boreal trees and shrubs must have existed as small refugial populations during the LGM. In central and eastern Europe, [Willis and van Andel \(2004\)](#) argue, on the

basis of macrofossil charcoal from trees, that 20 different tree taxa were growing in the region during the last full-glacial interval. According to [Bhagwat and Willis \(2008\)](#), these trees survived in these northerly refugia due to specific biogeographical traits, such as short generation time, small seed size, and vegetative reproduction, and not by chance. In North America, it has been shown that broad-leaved trees were distributed more widely than first believed. Syntheses of pollen and macrofossil data show that boreal tree taxa and/or tundra were growing close to the Laurentide Ice margin during the LGM ([Jackson et al., 2000](#)). [Anderson et al. \(2006\)](#) have shown, from multiple lines of evidence including DNA and macrofossil analyses, that white spruce (*Picea glauca*) survived in glacial refugia in Alaska.

The Present Interglacial: The Holocene

In light of new macrofossil evidence, both for the LGM and the early Holocene, the postglacial vegetation migration rates of 500–1000 m year⁻¹ suggested by [Huntley and Birks \(1983\)](#) have been questioned by several authors (e.g., [Binney et al., 2009](#); [McLachlan et al., 2005](#)) because observations of mean dispersal distances of most trees and herbs are too small to account for these recolonization rates in northern latitudes, following retreat of the glaciers. This lack of consistency between migration rates derived from different biological data sets has been termed Reid's paradox ([Clark et al., 1998](#)). Resolving this issue has been a major task in recent paleoecological research.

With the new evidence from macrofossil data showing that many tree species survived in refugia further north, a more detailed picture of their postglacial migration routes and rates can be drawn ([Binney et al., 2009](#); [Väliranta et al., 2011](#)). The existence of these northern refugia can explain the rapid spread and expansion of trees in the early Holocene and thus also explain early finds of tree remains at high altitudes in Scandinavia ([Kullman, 1998](#)).

Past behavior of the treeline is also of interest because it is linked to large-scale climate features ([Binney et al., 2009](#)). Altitudinal and latitudinal Holocene treeline changes in relation to climate change have been studied extensively in many areas, based both on pollen and macrofossils (e.g., [Binney et al., 2009](#); [Bjune, 2005](#); [Hooghiemstra and Van der Hammen, 2004](#); [MacDonald et al., 2000](#); [Payette et al., 2002](#)). In addition to climate, the spatial and temporal variations in treeline are also related to tree dispersal rates and distances to glacial refugia. From LGM to mid-Holocene, latitudinal treelines in Europe migrated north more than 2000 km from areas close to the Alps to northern parts of Scandinavia ([Willis et al., 2000](#)). Similar trends are seen in the Colombian Andes ([Hooghiemstra and Van der Hammen, 2004](#); [Van der Hammen, 1974](#)). In addition to latitudinal changes in the treeline, large changes have been observed in the altitudinal treeline in Scandinavia (e.g., [Barnekow, 1999](#); [Bjune, 2005](#); [Kullman, 1998](#)) as well as in the Alps (e.g., [Tinner and Kaltenrieder, 2005](#)) in the early and middle part of the Holocene. The pattern of treeline movements in North America differed somewhat from that of Eurasia. Trees migrated north through Canada rather late, because these areas only became free of ice in

the mid-Holocene in some cases. Most of these forest trees spread toward northern areas from a large southern refugium (Payette et al., 2002).

One significant recent ecosystem change is the establishment of spruce (*Picea abies*) forest in southern Scandinavia in the later part of the Holocene. This led to a switch in keystone species in the forests, as spruce replaced the existing forests dominated by birch (*Betula*) and/or pine (*Pinus sylvestris*) in some areas and broad-leaved forests in others (e.g., Bjune et al., 2009; Giesecke, 2005; Giesecke and Bennett, 2004; see **Changing Plant Distributions and Abundances**). During the last 5000–6000 years, small spruce populations expanded rapidly northward from areas close to the ice sheet (Giesecke, 2005; Giesecke and Bennett, 2004). Also, in northwest Russia, there is evidence for spruce growth at and beyond the present-day treeline at the onset of the Holocene (Väliranta et al., 2011).

Future

It is evident from the fossil and genetic records that species have changed their distribution as a reaction to climate and this will happen in the future as well. Understanding how plant distribution and biodiversity have responded to past environmental factors, including climate change, natural disturbance, and human activities, is essential to predicting how plant distribution and diversity may change in response to global warming. The understanding of past responses gained through paleophytogeography and paleoecology is important for the prediction of future migration rates and distributional changes. This knowledge will also help determine regions with the highest genetic diversity, a factor that is important for the long-term persistence and conservation of plant species. Paleoecological data also allow comparisons between present-day ecological dynamics and dynamics before human impact. Closer integration of data sets and more high-resolution analyses will improve the quality and extend the applicability of paleoecological data.

To fully utilize data from the past, much can be gained by combining traditional paleoecological data with new techniques such as molecular methods and climate and population modeling. Genetic data provide an effective approach to detect cryptic refugia (Anderson et al., 2006), population sizes, and lineages of ancestry but are, relative to paleoecological data, less accurate in providing evidence of timing and location. Extracting DNA from the fossil records, such as fossil pollen, can answer questions on plant migration in space and time at a high taxonomic level (MacDonald et al., 2008). Modeling will be important to estimate potential climatic and ecological forcing mechanisms. Ecological models and simulations will provide tests of dynamic responses of vegetation to climate changes and are thus important for conservation and management.

Silicon Isotopes in Diatoms

J J Tyler, The University of Oxford, Oxford, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Silicon isotope analysis of diatom silica ($\delta^{30}\text{Si}_{\text{diatom}}$) is a rapidly evolving technique for tracking changes in silicon uptake by diatoms within both marine and freshwater environments. In combination with other isotopic proxies, $\delta^{30}\text{Si}_{\text{diatom}}$ can provide an alternative insight into biogeochemical cycles of the past. To date, $\delta^{30}\text{Si}_{\text{diatom}}$ measurements have played a key role in formulating and testing hypotheses concerning phytoplankton export of carbon to the deep ocean, with implications for understanding the long-term controls over the global carbon cycle (Beucher et al., 2007; Brzezinski et al., 2002; De La Rocha et al., 1998; Pichevin et al., 2009). $\delta^{30}\text{Si}_{\text{diatom}}$ also has potential for tracking environmental change using lake sediments, either as a proxy for diatom biogeochemistry, or as a tracer of past changes in the inorganic silicon cycle, related to past weathering processes in hydrological systems (Alleman et al., 2005; Street-Perrott et al., 2008; Swann et al., 2010).

Silicon is the second most abundant element on Earth, with three major stable isotopes, ^{28}Si , ^{29}Si , and ^{30}Si , with abundances of 92.22, 4.68, and 3.08%, respectively (Rosman and Taylor, 1998). Silicon isotope ratios are reported as either $\delta^{29}\text{Si}$ or $\delta^{30}\text{Si}$, whereby:

$$\delta^{30}\text{Si} = 1000 \left(\frac{R_{\text{Sample}} - R_{\text{Std}}}{R_{\text{Std}}} \right) \quad [1]$$

where R is the $^{30}\text{Si}/^{28}\text{Si}$ (or $^{29}\text{Si}/^{28}\text{Si}$ for $\delta^{29}\text{Si}$) ratio of either the sample or standard (NBS-28), as indicated by the subset label. Today, majority of techniques allow measurement of $\delta^{30}\text{Si}$; however, analytical limitations with some methods require instead the use of $\delta^{29}\text{Si}$ (e.g., Cardinal et al., 2003; De La Rocha, 2002). Because silicon isotope fractionation is mass dependent, $\delta^{30}\text{Si}$ can be estimated from $\delta^{29}\text{Si}$ as (Cardinal et al., 2003; De La Rocha, 2002):

$$\delta^{30}\text{Si} = \delta^{29}\text{Si} \times 1.93 \quad [2]$$

Diatoms assimilate and polymerize hydrous silica ($\text{Si}[\text{OSi}]_n[\text{OH}]_{4-n}$) from silicic acid ($\text{Si}[\text{OH}]_4$) to form the distinctive silica frustules which distinguish them from other microalgae and which accumulate in marine and lacustrine deposits. The fundamental origin of silicic acid is the dissolution of silicate minerals, transported to the lake or marine environment via airborne dust, rivers, or groundwater (Basile-Doelsch, 2006; De La Rocha and Bickle, 2005; De La Rocha et al., 2000). In many cases, a large percentage of the silicic acid available to diatoms originates from the dissolution of sedimenting diatom frustules (e.g., Alleman et al., 2005; Treguer et al., 1995). The pathway by which silicic acid reaches the environments in which diatoms grow can have a significant effect on the isotopic composition of the silicic acid and subsequent isotopic composition of diatom silica. Therefore, $\delta^{30}\text{Si}_{\text{diatom}}$ is a function of the silicon isotope composition of dissolved silica/silicic acid ($\delta^{30}\text{Si}_{\text{DSi}}$), the amount of silicic acid

uptake by diatoms, and the isotopic fractionation between the silicic acid and diatom silica (De La Rocha et al., 1997, 2000). Consequently, understanding the $\delta^{30}\text{Si}_{\text{diatom}}$ of sedimentary deposits requires an appreciation of both the processes that control the transport of silicic acid to diatom habitats, and those which affect the uptake of silicic acid by diatoms. Because silicon isotopes can be used as a proxy for past changes in diatom productivity, the biological effects over $\delta^{30}\text{Si}_{\text{diatom}}$ have attracted the most attention (Brzezinski et al., 2002; De La Rocha et al., 1997, 1998; Pichevin et al., 2009). However, there is also potential for using $\delta^{30}\text{Si}_{\text{diatom}}$ as a proxy for past changes in weathering and transport of nutrients to aquatic systems (Georg et al., 2009a; Street-Perrott et al., 2008; Swann et al., 2010). This article aims to detail the most important aspects of silicon isotope variability in the contemporary environment, while demonstrating the considerable potential for using $\delta^{30}\text{Si}_{\text{diatom}}$ in Quaternary research. Additional reviews on silicon isotopes, in diatoms, other organisms and inorganic systems are presented by De La Rocha (2006), Leng et al. (2009), and Basile-Doelsch (2006).

Analytical Procedures

As is the case with the oxygen isotope composition of diatoms ($\delta^{18}\text{O}_{\text{diatom}}$) $\delta^{30}\text{Si}_{\text{diatom}}$ analysis requires samples of pure diatom silica, free of any minerogenic or organic contamination. The procedures for purification of diatom silica and quantification of contaminants largely mirror those for $\delta^{18}\text{O}_{\text{diatom}}$, and are thus not covered here. It has been suggested that $\delta^{30}\text{Si}_{\text{diatom}}$ preparation requires the avoidance of glassware, which can be a source of contamination. In addition, some researchers involve extra trace metal cleaning steps prior to isotope analysis, which may be beneficial in stripping the diatoms of externally attached clay particles and other contaminating oxides (e.g., Hendry et al., 2010). While $\delta^{18}\text{O}_{\text{diatom}}$ is more sensitive to sample preparation temperature, reagent and heating time, the primary concern with $\delta^{30}\text{Si}_{\text{diatom}}$ is avoidance of sample dissolution, which can lead to isotopic bias (Demarest et al., 2009).

A number of methods exist for the measurement of $\delta^{30}\text{Si}$ from particulate diatom silica and dissolved silicic acid (Leng et al., 2009; Reynolds et al., 2007). These include: fluorine based conversion of silica into SiF_4 and isotope ratio mass spectrometry (IRMS) (De Freitas et al., 1991; De La Rocha et al., 1996; Ding et al., 1996; Leng and Sloane, 2008), multiple collector inductively coupled plasma mass spectrometry (MC-ICP-MS; Cardinal et al., 2003; De La Rocha, 2002; Reynolds et al., 2006b), acid decomposition and IRMS (Brzezinski et al., 2006), and secondary ion mass spectrometry (SIMS) (Basile-Doelsch et al., 2005). An interlaboratory comparison study found that each of the different methods generate identical values within analytical error

(Reynolds et al., 2007), with reproducibility typically between 0.05 and 0.1‰ for all methods except SIMS.

Fluorination

Fluorination methods involve the conversion of silica into SiF_4 using a fluorine based reagent, such as ClF_3 or BrF_5 (De La Rocha et al., 1996; Douthitt, 1982; Leng and Sloane, 2008; Tilles, 1961). The silica sample is reacted in three steps, and subsequently the Si is extracted. Stage one involves ‘outgassing’ (dehydration) to remove surficial and loosely bonded water in the reaction tubes at room temperature. Stage two involves a prefluorination step involving a stoichiometric deficiency of the reagent at low temperatures which removes hydroxyl and loosely bound water. The third stage is a full reaction at 450 °C for around 12 h with an excess of reagent to disassociate the silica into O_2 and SiF_4 . Isotopes are subsequently measured by IRMS. Advantages of using fluorination include the ability to measure oxygen and silicon isotopes from the same sample (Leng and Sloane, 2008), while recent developments using a laser microprobe offer the potential to analyze individual diatom frustules (Gao and Ding, 2009).

Multiple Collector Inductively Coupled Plasma Mass Spectrometry

MC-ICP-MS, operating in either wet or dry plasma mode, offers the option to avoid using fluorine reagents (Cardinal et al., 2003; De La Rocha, 2002; Georg et al., 2006b; Reynolds et al., 2006b). Reliable silicon isotope measurements can be obtained with analytical errors that are equivalent to or lower than those achieved using fluorination from much smaller samples. Further improvements in sensitivity and reproducibility have been made by dissolving the silica either in aqueous NaOH or by alkaline fusion followed by cation exchange chromatography to purify Si for analysis (Georg et al., 2006b; van den Boorn et al., 2006). When operating at normal resolution, MC-ICP-MS is limited by atomic interference over the Si mass range, predominantly from $^{14}\text{N}^{16}\text{O}$ which has a mass of 30. In such circumstances, only $\delta^{29}\text{Si}$ can be calculated (Cardinal et al., 2003; De La Rocha, 2002). High resolution MC-ICP-MS eliminates the effects of any interference and allows direct measurement of $\delta^{30}\text{Si}$ (Chmeleff et al., 2008; Reynolds et al., 2006b).

Acid Decomposition

The acid decomposition method enables part automation of sample preparation and analysis, using a modified Finnigan Kiel device and IRMS (Beucher et al., 2007, 2008; Brzezinski et al., 2006). Silica samples of high purity are converted to Cs_2SiF_6 by dissolution in HF and the addition of CsCl. Using the modified Kiel device, the Cs_2SiF_6 product is decomposed in sulfuric acid to generate SiF_4 gas online with a gas source isotope ratio mass spectrometer for analysis. Samples that contain significant levels of nonsiliceous impurity can be pre-processed by dissolution in HF followed by precipitation of

triethylamine silicomolybdate and combustion of the precipitate to generate SiO_2 , following De La Rocha et al (1996) (Brzezinski et al., 2006).

Secondary Ion Mass Spectrometry

SIMS is predominantly used for analysis of mineral grains, however, the ability to analyze particles larger than ~50 µm diameter offers the potential for analysis of individual diatom frustules (Alexander et al., 2002; Basile-Doelsch et al., 2005). SIMS requires polished thin sections and individual grains must be mounted in epoxy resin prior to analysis. In terms of analytical precision, SIMS measurements are less precise ($\pm 0.75\%$ (2σ)). However, an improvement in analytical precision would offer great potential in terms of examining the isotopic homogeneity of sediment samples, identifying species-specific isotope ratios, or for obtaining high resolution isotope records using extremely small samples.

Fractionation of Silicon Isotopes During Diatom Growth

Central to the use of $\delta^{30}\text{Si}_{\text{diatom}}$ as a biogeochemical tracer is the preferential assimilation by diatoms of the lighter ^{28}Si over ^{30}Si during synthesis of their silica frustules. As a result of this isotopic discrimination, uptake of silicic acid from the substrate leads to a progressive increase in the $\delta^{30}\text{Si}$ of residual silicic acid and a corresponding increase in the $\delta^{30}\text{Si}$ of subsequent diatom silica (Figure 1). Therefore, on a first order, there is a positive relationship between the amount of silica used by diatoms, the isotopic composition of dissolved silicon ($\delta^{30}\text{Si}_{\text{DSi}}$), and the isotopic composition of the diatoms ($\delta^{30}\text{Si}_{\text{diatom}}$; Figure 1). The discrimination by diatoms against ^{30}Si is expressed in terms of the fractionation factor (ϵ), which is approximately equal to the difference in δ between the dissolved and particulate phase:

$$\epsilon = 1000 \times \ln \left(\frac{R_{\text{DSi}}}{R_{\text{diatom}}} \right) \approx \delta^{30}\text{Si}_{\text{DSi}} - \delta^{30}\text{Si}_{\text{diatom}} \quad [3]$$

De La Rocha et al. (1997) estimated ϵ as -1.1% , independent of species and growth temperature, based on culture experiments using three species of marine phytoplankton: *Skeletonema costatum*, *Thalassiosira weissflogii*, and *Thalassiosira* sp. These findings are supported by an earlier study by Spadero (1983) who estimated a similar value of ϵ for *Phaeodactylum tricornutum* and by Milligan et al (2004), who cultured *T. weissflogii* across a range of dissolved CO_2 concentrations. To date, it is unclear when and where silicon isotopic fractionation occurs within the diatom cell during silicification. However, because changes in dissolved CO_2 concentration affect the amount of silica polymerization by *T. weissflogii*, but not $\delta^{30}\text{Si}_{\text{diatom}}$, it appears that the isotopic fractionation does not take place during the polymerization step (Milligan et al., 2004). Further studies such as this are required in order to develop a mechanistic perspective of silicon isotope fractionation by diatoms. For example, the four species of marine phytoplankton examined so far represent a narrow group with respect to the diversity of diatoms and the range of habitats in which they exist (Round et al., 1990). In particular, there are no

Figure 1 Conceptual models for isotope fractionation between silicic acid (dissolved silicon) and diatom silica. (a) Rayleigh distillation within a closed system, assuming a single initial silicic acid source with no replenishment. (b) Isotope fractionation in a steady state open system, assuming constant replenishment of the silicic acid substrate, balanced by constant removal of diatom silica. In equations, f = fraction of dissolved silica remaining; $\delta^{30}\text{Si}_{\text{DSi}}$ = silicon isotope composition of dissolved silicon; $\delta^{30}\text{Si}_{\text{DSi, initial}}$ = initial $\delta^{30}\text{Si}_{\text{DSi}}$ at $f=1$; $\delta^{30}\text{Si}_{\text{diatom, inst.}}$ = instantaneous $\delta^{30}\text{Si}$ of diatom silica; $\delta^{30}\text{Si}_{\text{diatom, acc.}}$ = cumulative $\delta^{30}\text{Si}$ of diatom silica.

controlled estimates for isotope fractionation at temperatures relevant to the Southern Ocean, which is an important region for diatom productivity. Nor have there been any culture based studies of freshwater diatoms, despite a marked difference in silicification between freshwater and marine taxa (Conley et al., 1989).

Beyond the laboratory, the validity of $\delta^{30}\text{Si}_{\text{diatom}}$ as a biogeochemical tracer has been investigated by monitoring the natural environment. At first glance, the three dimensional distribution of $\delta^{30}\text{Si}_{\text{DSi}}$ in the ocean appears to conform with culture observations, whereby high $\delta^{30}\text{Si}_{\text{DSi}}$ values are found in regions of low silicic acid concentration due to uptake by diatom growth (e.g., Figure 2; Reynolds et al., 2006a). Surface transects and depth profiles have been studied in the Southern Ocean (Cardinal et al., 2005, 2007; De La Rocha et al., 2000; Varela et al., 2004), Monterey Bay, California (De La Rocha et al., 2000), the north

Pacific (Reynolds et al., 2006a) and the eastern equatorial Pacific (Beucher et al., 2008). In general, these studies support a -1.1‰ fractionation factor, however, such estimates come with a high degree of uncertainty due to poor control over the source and isotopic composition of the silicic acid used by the diatoms.

In particular, elucidating isotope fractionation (ϵ) from field samples is hampered by a lack of control over the degree of mixing between water bodies of different Si concentration and isotopic composition, and this process alone can explain the distribution observed in Figure 2 (Reynolds et al., 2006a). Because the majority of Si entering the ocean is assimilated by diatoms, which subsequently dissolve during sedimentation, the $\delta^{30}\text{Si}$ of the deep ocean has a largely homogenous $\delta^{30}\text{Si}$ of $+0.9\text{‰}$ roughly equal to that of the sum of inputs to the ocean (De La Rocha and Bickle, 2005; De La Rocha et al., 2000). Upwelling of this deep ocean silicic acid provides

Figure 2 Variations in North Pacific seawater $\delta^{30}\text{Si}$ correlate with nutrient concentrations (in μM) due to mixing of nutrient depleted surface water with nutrient replete deep waters. Plotted as $\ln[\text{phosphate}]$ in black diamonds, $\ln[\text{nitrate}]$ in gray squares, and $\ln[\text{Si}(\text{OH})_4]$ in open circles with right axis (Reynolds et al., 2006a).

the raw material upon which diatom silicification depends, however in order to estimate ϵ from natural variations in $\delta^{30}\text{Si}$, an assumption is required either that the diatoms grew (a) in a closed system, whereby an initial pool of silicic acid is progressively assimilated with no further replenishment (as in batch culture), in which case isotope fractionation follows a Rayleigh-type distillation curve (Figure 1(a)), or (b) within an open system under steady state with continuous supply of Si and removal of diatoms (Figure 1(b); Cardinal et al., 2007; De La Rocha et al., 1997; 2000; Varela et al., 2004). For example, Varela et al. (2004) measured $\delta^{30}\text{Si}_{\text{DSi}}$ and $\delta^{30}\text{Si}_{\text{diatom}}$ from surface water samples in the Southern Ocean and generated estimates for ϵ using both open and closed system models which ranged between +1 and +2.1‰ depending on the parameters used (Varela et al., 2004). A similar comparison by Cardinal et al. (2007) suggests a correlation between ϵ and silicic acid concentration. However, uncertainties over the effect of mixing hampers attempts to rigorously validate the isotope fractionation factor using field comparisons, as well as raising uncertainty in interpreting paleo- $\delta^{30}\text{Si}_{\text{diatom}}$ changes.

Fractionation of Silicon Isotopes During Diatom Dissolution

Recycling of diatom silica is a key component of the global silicon cycle, with for example, 97% of diatoms living in the marine photic zone lost via dissolution during sinking (Ragueneau et al., 2000; Treguer et al., 1995). Dissolution

can also have a significant effect on diatom sedimentation and silicon cycling within lakes, particularly saline lakes and deep lakes such as Lake Baikal. Little is known about the effects of taphonomic processes, such as dissolution on the $\delta^{30}\text{Si}$ of sedimentary diatoms (Demarest et al., 2009). De La Rocha et al. (1998) reported an absence of any change in $\delta^{30}\text{Si}_{\text{diatom}}$ following a 26% dissolution of opal frustules. However, a more detailed experimental study reported that a systematic isotope effect accompanied the dissolution of diatom silica, with the accumulating dissolved silicon being consistently depleted in ^{30}Si by $\sim 0.55\%$ relative to the corresponding residual silica (Demarest et al., 2009; Figure 3). This fractionation, which essentially acts to reverse that which occurs during diatom growth, was unaffected by differences in temperature, sample composition or solubility (Demarest et al., 2009; Figure 3).

The implications of these findings are widespread. For example, dissolution could affect the spatial distribution of $\delta^{30}\text{Si}_{\text{DSi}}$ in the ocean, a process which has not been taken into account within existing models (e.g., Reynolds, 2009; Reynolds et al., 2006a; Wischmeyer et al., 2003). In addition, unknown dissolution effects will have compromised attempts to calibrate ϵ from field studies (Cardinal et al., 2005, 2007; De La Rocha et al., 2000; Reynolds et al., 2006a; Varela et al., 2004) and may explain apparent spatial variability in ϵ (Cardinal et al., 2007). Importantly, the effects of dissolution can also lead to an overestimation of past silicon utilization from sedimentary $\delta^{30}\text{Si}_{\text{diatom}}$ data (Demarest et al., 2009), particularly if the amount of dissolution changed with time. Demarest et al. (2009) suggest that given the analytical uncertainty of $\sim 0.1\%$ for $\delta^{30}\text{Si}$ measurements, dissolution differences of less than $\sim 20\%$ between samples are unlikely to impose measureable bias in their respective $\delta^{30}\text{Si}_{\text{diatom}}$. In addition, despite the large amount of silica lost to dissolution within the ocean (Treguer et al., 1995), it is possible that the diatoms which remain have undergone minimal dissolution (Demarest et al., 2009). Nevertheless, it is clear that attempts to quantify the amount of dissolution of diatom samples should be given a high priority in future research projects.

Factors Affecting Silicon Isotopes in Terrestrial Hydrological Systems

An understanding of the non-diatom related processes that affect $\delta^{30}\text{Si}_{\text{DSi}}$ in water is needed before sedimentary records of $\delta^{30}\text{Si}_{\text{diatom}}$ can be interpreted. An increasingly large volume of work has documented the wide natural variability of $\delta^{30}\text{Si}_{\text{DSi}}$ in terrestrial hydrological systems such as groundwaters, soil water, and rivers. Inorganic processes such as dissolution of crustal rock, precipitation of secondary minerals, adsorption of silicic acid onto secondary oxides of iron and aluminum, and subsequent dissolution of secondary minerals and oxides, present a complex array of factors which can alter the $\delta^{30}\text{Si}$ of silicic acid entering lakes and oceans (Basile-Doelsch, 2006; De La Rocha et al., 2000; Douthitt, 1982). Generally speaking, the $\delta^{30}\text{Si}_{\text{DSi}}$ of river water is usually higher than that of crustal rock (De La Rocha et al., 2000; Ding et al., 2004; Georg et al., 2006a). By contrast, secondary precipitates, adsorbed silicic acid and higher plant biogenic silica (phytoliths) have $\delta^{30}\text{Si}$

Figure 3 Effects of silica dissolution on $\delta^{30}\text{Si}_{\text{diatom}}$. Silicon isotope composition of residual diatom silica (open symbols) and accumulating $\text{Si}(\text{OH})_4(\text{aq})$ (filled symbols) as a function of the fraction of Southern Ocean surface water diatom silica dissolved during (a) single batch and (b) serial stage dissolution experiments in a closed system, as compared to expectations for an open kinetic/equilibrium (left panels) or closed kinetic Rayleigh (right panels) fractionation process. Squares, diamonds and triangles reflect different experiments and lines indicate the isotope trends expected for each open kinetic or equilibrium models (see Demarest et al., 2009 for details).

values lower than bedrock (Basile-Doelsch et al., 2005; Ding et al., 2008; Opfergelt et al., 2009). Subsequent dissolution of secondary minerals and biogenic silica therefore generates silicic acid with lower $\delta^{30}\text{Si}$ than that derived from primary weathering. Therefore, the $\delta^{30}\text{Si}_{\text{DSi}}$ of water entering lakes and oceans can largely be explained by the relative influence of these different silicon sources and pathways (Georg et al., 2006a, 2009a).

For example, in the Verzasca River, Switzerland, high $\delta^{30}\text{Si}_{\text{DSi}}$ was observed to correspond with periods of low discharge and high base cation flux (Georg et al., 2006a). This was interpreted to be due to isotopic fractionation during precipitation of secondary clays within shallow groundwaters and soils. By contrast, periods of high river discharge had low $\delta^{30}\text{Si}$ and low base cation flux characteristic of overland runoff, where the low $\delta^{30}\text{Si}_{\text{DSi}}$ values reflect the original weathering of crustal bedrock (Georg et al., 2006a). Groundwaters in the Bengal Basin, India (Georg et al., 2009a), and in the Navajo Sandstone aquifer, Arizona (Georg et al., 2009b) were found to have low $\delta^{30}\text{Si}_{\text{DSi}}$ (as low as -1.42‰ in Arizona, -0.2‰ in Bengal) relative to regional river waters; however, their silicic acid concentration was higher. These low $\delta^{30}\text{Si}_{\text{DSi}}$ values were interpreted to reflect dissolution of secondary clays or silcretes within the aquifer leading to a progressive decrease in $\delta^{30}\text{Si}_{\text{DSi}}$ along the flowpath (Georg et al., 2009b). Where biological

uptake plays an important role in the silicon cycle, interpreting the $\delta^{30}\text{Si}_{\text{DSi}}$ of freshwaters becomes increasingly complex and difficult to disentangle (Georg et al., 2006a). In heavily vegetated systems, assimilation of silica by higher plants can have a significant effect on the $\delta^{30}\text{Si}_{\text{DSi}}$ in river water (e.g., Ding et al., 2004).

Applications of $\delta^{30}\text{Si}_{\text{diatom}}$ to Quaternary Marine Sediments

Understanding temporal patterns in marine primary productivity and organic carbon drawdown is critical for understanding glacial–interglacial changes in atmospheric $p\text{CO}_2$. In this respect, studies of marine $\delta^{30}\text{Si}_{\text{diatom}}$ records have had a significant impact, despite uncertainties concerning the controls over silicon isotopes in the contemporary environment (Beucher et al., 2007; Brzezinski et al., 2002; De La Rocha et al., 1998; Hendry et al., 2010; Pichevin et al., 2009). For example, $\delta^{30}\text{Si}_{\text{diatom}}$ records from sediments collected south of the Antarctic polar front show declines of $\sim 1\text{‰}$ at the onset of the Last Glacial Maximum (LGM; De La Rocha et al., 1998) and several previous glacials (Brzezinski et al., 2002; Figure 4). One interpretation is that these data reflect a reduction in diatom productivity in the Southern Ocean during glacial maxima due

Figure 4 Southern Ocean sediments demonstrate enhanced silicic acid uptake during glacial periods, inversely correlated with nitrate utilization ($\delta^{15}\text{N}$; Brzezinski et al., 2002), $\delta^{18}\text{O}$ (*N. pachyderma*; Charles et al., 1991), opal content (Charles et al., 1991), $\delta^{30}\text{Si}$ of diatom opal and $\delta^{15}\text{N}$ of bulk sediment (Rau and Froelich, 1993) from RC13-259 (53°53' S; 4°56' W; 2677 m). Numbers indicate oxygen isotope stages 1–10 (Brzezinski et al., 2002). Gray shading indicates interglacial periods.

to expansion of sea ice cover (De La Rocha et al., 1998). However, the $\delta^{30}\text{Si}_{\text{diatom}}$ evidence contrasts with the nitrogen isotope ratio of organic matter ($\delta^{15}\text{N}_{\text{org}}$; Figure 4), which suggest an increase in nitrate utilization (increased productivity) during the glacials (Brzezinski et al., 2002). This inverse relationship between $\delta^{30}\text{Si}_{\text{diatom}}$ and $\delta^{15}\text{N}_{\text{org}}$ can be explained by a reduction of silicon uptake in diatoms relative to carbon and nitrogen assimilation due to increased iron availability during glacial periods (Hutchins and Bruland, 1998). Today, the Southern Ocean is iron limited and the ratio of Si:N uptake by phytoplankton is ~4:1 (Pondaven et al., 2000). However, under saturating light and nutrient conditions, and during Fe fertilization experiments, ratios of ~1:1 have been observed (Coale et al., 2004). It is proposed that desert expansion during glacial maxima increased the flux of iron-rich eolian dust which fertilized the ocean. However, although productivity (carbon and nitrogen uptake) increased, the higher iron concentration led to a reduction in diatom silicic acid uptake (Figure 4; Brzezinski et al., 2002; Matsumoto et al., 2002).

One potential outcome of this proposed decoupling between primary productivity and silicification during glacial maxima is an excess of unused silicic acid within the Southern Ocean surface waters. The silicic acid leakage hypothesis (Brzezinski et al., 2002; Matsumoto et al., 2002) proposes that this excess silicon was transported northwards, via the sub-Antarctic mode water, where it provided a competitive advantage to diatoms over coccolithophores in the mid- to low latitudes. In turn, this led to a global reduction in calcite biomineralization, raising ocean alkalinity and increasing atmospheric CO_2 drawdown (Brzezinski et al., 2002; Matsumoto et al., 2002). In support of this hypothesis, a sediment core from the sub-Antarctic sector of the Indian Ocean exhibits decreases in $\delta^{30}\text{Si}_{\text{diatom}}$ which suggest that excess silicic acid reached this site during the LGM (Beucher et al., 2007). However, similar changes in $\delta^{30}\text{Si}_{\text{diatom}}$ are not apparent in the subtropics, making it unclear whether the pool of silicic acid extended into the subtropical region during glacial periods (Beucher et al., 2007; Crosta et al., 2007).

Silicon leakage may have also occurred from the tropical Pacific Ocean during glacial times. Iron fertilization via

airborne dust is invoked to explain low $\delta^{30}\text{Si}_{\text{diatom}}$ values during the LGM in the Eastern Equatorial Pacific (Pichevin et al., 2009). In this instance, a reduction in biogenic silica sedimentation rate, alongside lower $\delta^{30}\text{Si}_{\text{diatom}}$ values, coincides with an increase in the deposition of organic carbon during the LGM, indicating enhanced carbon export during this period (Figure 5). Estimated silicic acid and nitrate uptake rates, based on silicon and nitrogen isotopes, suggest that neither of these nutrients limited productivity during the LGM (Pichevin et al., 2009). Instead, it is possible that phosphate may have played a limiting role in the tropical glacial ocean, which is a marked contrast to the situation in the contemporary ocean (Pichevin et al., 2009).

Although interpretations of $\delta^{30}\text{Si}_{\text{diatom}}$ such as these are compelling, alternative explanations can be offered to explain variability in $\delta^{30}\text{Si}_{\text{diatom}}$ over Quaternary timescales. One major limitation to using $\delta^{30}\text{Si}$ as a proxy for past diatom productivity is the potential variability in the concentration and $\delta^{30}\text{Si}$ of upwelling silicic acid. At present, the deep ocean is thought to be isotopically homogenous (Cardinal et al., 2005), however given that the oceanic residence time of Si is roughly 15000 years (Treguer et al., 1995) and a full glacial-interglacial cycle covers 100000 years, some portion of the observed variability in $\delta^{30}\text{Si}_{\text{diatom}}$ may be due to changes in the flux of silicon to the ocean via terrestrial weathering. The concentration of silicic acid in upwelling waters can be estimated using the $\delta^{30}\text{Si}$ of benthic sponge spicules (Hendry et al., 2010; Wille et al., 2010). Sponge spicule $\delta^{30}\text{Si}$ records from sediments beneath the Southern Ocean appear to demonstrate that the concentration and $\delta^{30}\text{Si}_{\text{DSi}}$ of upwelling water at the LGM exhibited no significant difference from contemporary conditions (Ellwood et al., 2010; Hendry et al., 2010), thus supporting the interpretation of $\delta^{30}\text{Si}_{\text{diatom}}$ as a proxy for silicic acid uptake in the photic zone (Ellwood et al., 2010; Hendry et al., 2010).

Additional uncertainties concern the effect of species change on $\delta^{30}\text{Si}_{\text{diatom}}$, since any major shift in the biogeochemistry of surface waters will undoubtedly be accompanied by a floristic shift (De La Rocha, 2006). Although culture experiments have demonstrated no significant difference between the isotopic fractionation by different taxa (De La Rocha et al., 1997) changes in diatom species, associated with different bloom forming patterns and seasonal preferences, could lead to seasonal bias within sedimentary $\delta^{30}\text{Si}_{\text{diatom}}$ records. Such issues could be addressed by species-specific analyses of diatom remains. Alternatively, where laminated sediments are available, microstratigraphic analysis on a subannual scale would enable an estimate of the seasonal weighting given by different species, relative to the bulk sample.

$\delta^{30}\text{Si}_{\text{diatom}}$ in Lakes and Lake Sediments

To date, very little research has been published on silicon isotopes in either lakes or lake sediments. Alleman et al. (2005) investigated the seasonal pattern of $\delta^{29}\text{Si}_{\text{DSi}}$ in Lake Tanganyika, in conjunction with analyses of tributary waters and five $\delta^{29}\text{Si}_{\text{diatom}}$ measurements from lake diatom phytoplankton. In addition, Street-Perrott et al. (2008) and Swann et al. (2010) generated late-glacial and Holocene

$\delta^{30}\text{Si}_{\text{diatom}}$ records from Lake Rutundu, Kenya and Lake El'gytgytyn, Siberia, respectively. In principle, the processes which control lacustrine $\delta^{30}\text{Si}_{\text{diatom}}$ are the same as those that operate in the ocean (Alleman et al., 2005); thus, there is potential to use silicon isotopes to trace aquatic biogeochemical change in freshwaters, with significance for understanding global and regional carbon cycling (Street-Perrott and Barker, 2008). However, while the deep ocean environment can be considered to be buffered against short-term variability in terrestrial inputs and processes (De La Rocha and Bickle, 2005), the small volume of lakes, and their short residence time for Si, leads to a much greater sensitivity to silicon isotope changes originating from the surrounding catchment (Street-Perrott et al., 2008). Lake $\delta^{30}\text{Si}_{\text{diatom}}$ records could therefore offer a valuable archive of changes in terrestrial weathering processes.

Large lakes are more likely to yield data relevant to our understanding of freshwater biogeochemical silicon cycling in the past, as their greater silicon and water residence times mean the system is more analogous to the marine environment. For example, the long residence time of silica within Lake Tanganyika means that the surface silica budget is largely a function of vertical mixing and silicon recycling, while Si loading from tributaries accounts for 2–3% at most (Alleman et al., 2005). Water depth $\delta^{29}\text{Si}$ profiles from Lake Tanganyika are similar to those analyzed in sea water, with low $\delta^{29}\text{Si}_{\text{DSi}}$ values in deep water (mean $\delta^{29}\text{Si}_{\text{DSi}} = +0.61 \pm 0.05\text{‰}$, calculated $\delta^{30}\text{Si}_{\text{DSi}} = 1.18\text{‰}$; eqn [2]) and high values in the epilimnion due to uptake of silicic acid by diatoms (Alleman et al., 2005). Biweekly monitoring of Si concentration and $\delta^{29}\text{Si}_{\text{DSi}}$ over 1 year demonstrated three periods of silicon transport to the lake, characterized by increases in Si concentration and low $\delta^{29}\text{Si}_{\text{DSi}}$ values, followed by a decrease in concentration and increase in $\delta^{29}\text{Si}_{\text{DSi}}$ related to diatom productivity. In addition, a comparison between $\delta^{29}\text{Si}_{\text{diatom}}$ from five phytoplankton samples and $\delta^{29}\text{Si}_{\text{DSi}}$ from surrounding water generated estimates of ϵ close to the -1.1‰ reported for marine diatoms (Alleman et al., 2005).

Street-Perrott et al. (2008) conducted the first analyses of silicon isotopes from lake sediments as part of a multiproxy approach studying the terrestrial biogeochemical cycle of silicon at Lake Rutundu, Kenya. Between 37 and 18 ka, $\delta^{30}\text{Si}_{\text{diatom}}$ varied between -1.3 and $+0.5\text{‰}$, with most samples yielding near-maximum values, but with two notable minima at ~ 33 and 23 ka (Street-Perrott et al., 2008). The highest values of $+0.5\text{‰}$ fall within the expected range of surface runoff in this region, which could indicate complete utilization of silicic acid within the lake. However, the low $\delta^{30}\text{Si}_{\text{diatom}}$ values fall beyond the expected range for Rayleigh fractionation and possibly reflect enhanced groundwater influences on lake water (e.g., Georg et al., 2009a,b) during periods of low lake level (Street-Perrott et al., 2008).

Changes in $\delta^{30}\text{Si}_{\text{diatom}}$ within the sediments of Lake El'gytgytyn, Siberia, are interpreted as reflecting changes in silicic acid availability with time, owing to the restricted hydrological and weathering activity in this arctic region, and due to the oligotrophic nature of the lake (Swann et al., 2010). During the late-glacial and Holocene (~ 23 ka to present), $\delta^{30}\text{Si}_{\text{diatom}}$ exhibits marked changes – in particular higher values coinciding with the LGM (~ 20 ka) and Greenland Stadial 1 (a.k.a. Younger

Figure 5 A record of decreasing productivity but increasing silicification in the Eastern Equatorial Pacific during the transition from the Last Glacial Maximum (LGM) to the Holocene (Pichevin et al., 2009). Data from Core 1240, taken in the eastern Pacific Ocean, west of Equator. T1 = termination 1.

Figure 6 Climate and environmental change in north-eastern Siberia (Swann et al., 2010), as recorded by changes in (a) $\delta^{30}\text{Si}_{\text{diatom}}$ and (b) $\delta^{18}\text{O}_{\text{diatom}}$ in Lake El'gygytyn; (c) corresponding record from Greenland for comparison, NGRIP $\delta^{18}\text{O}_{\text{ice}}$ (NGRIP Project Members, 2004); (d) diatom species biovolumes; (e) diatom sample purity in the analyzed material and (f) ^{14}C age model for site Lz1029. Gray line for $\delta^{18}\text{O}_{\text{ice}}$ indicates the original NGRIP data, black line is a local polynomial regression (Loess) used to estimate comparable values of $\delta^{18}\text{O}_{\text{ice}}$ for the $\delta^{18}\text{O}_{\text{diatom}}$ data using a smoothing window to reflect the resolution of the sediment record. Age model uses a linear interpolation between calibrated ^{14}C dates (plotted) that incorporate a 1.3 ka reservoir effect correction. HTM on zonation indicates duration of 'Holocene thermal maximum' in Lake El'gygytyn. GS-1 indicates the short period of climatic cooling in Lake El'gygytyn that occurs during the GS-1 event in the Greenland ice core record.

Dryas; ~ 12.5 ka). Low $\delta^{30}\text{Si}_{\text{diatom}}$ values coincide with relatively warmer periods, namely the Holocene Thermal Maximum (10–9 ka BP; Swann et al., 2010). Swann et al. (2010) argue that during cold climates, deep permafrost, reduced weathering and limited moisture availability resulted in lower concentrations but a more complete consumption of silicic acid, which in turn led to higher $\delta^{30}\text{Si}_{\text{diatom}}$ values (Figure 6).

Analysis of $\delta^{30}\text{Si}_{\text{diatom}}$ from lake sediments offers considerable potential for obtaining extra information regarding the biogeochemical cycles of paleo- and contemporary lakes, in particular, when coupled with other isotopic and microfossil proxies. The ability to analyze $\delta^{30}\text{Si}_{\text{diatom}}$ alongside $\delta^{18}\text{O}_{\text{diatom}}$ using the same sample (Leng and Sloane, 2008) is likely to result in a marked increase in applications using lake sediments. However, continued research into $\delta^{30}\text{Si}$ patterns within contemporary lakes is required in order to better understand the relative controls over the isotope ratios in the sedimentary record.

Conclusion

Understanding changes in weathering, nutrient cycles and the cycling of carbon within aquatic systems is one of the key objectives of Quaternary research, due to the importance of these processes in driving global climate change. In this respect, silicon isotope analysis of diatom silica offers a valuable tool, particularly within a multiproxy framework. Where changes in the flux and isotopic composition of silicic acid remain constant with time, $\delta^{30}\text{Si}_{\text{diatom}}$ should reflect changes

in diatom silicic acid utilization (De La Rocha et al., 1997), dampened by the effects of diatom dissolution in some instances (Demarest et al., 2009). This interpretation of marine $\delta^{30}\text{Si}_{\text{diatom}}$ records has had considerable influence on the debate over the role of the oceanic carbon pump in driving long-term changes in atmospheric carbon dioxide concentration (e.g., Brzezinski et al., 2002). However, $\delta^{30}\text{Si}_{\text{diatom}}$ can also vary as a function of changes in the terrestrial silicon cycle (Basile-Doelsch, 2006), which potentially compromises the use of $\delta^{30}\text{Si}_{\text{diatom}}$ as a proxy for diatom silicic acid utilization. Such effects are particularly relevant where lake sediments are concerned, and in this respect, $\delta^{30}\text{Si}_{\text{diatom}}$ records may instead provide useful archives of past weathering processes and nutrient mobility (Street-Perrott et al., 2008). However, continued research into the controls over silicon isotopes in all facets of the contemporary environment is required in order to realize this potential.

PALEOCEANOGRAPHY

Paleoceanography An Overview

Introduction

Paleoceanographic records derived from marine sediment cores provide an ideal means to reconstruct climate and environmental change during the Quaternary. Deep sea sediment records are usually continuous and contain a mixture of terrigenous sediment (mostly clay) and plankton fossil remains, each providing many different proxies of environmental change ([Figure 1](#)). Typical deep sea sediments accumulate at rates of 1–5 cm ka⁻¹; a 10-m piston core contains a record of the past several hundred thousand years. Longer records are obtained from ocean drilling by the Deep Sea Drilling Project and its successors, the Ocean Drilling Program and Integrated Ocean Drilling Program. While initial sediment coring and deep sea drilling focused on the deep sea where accumulation rates are low, exciting progress in the past two decades has been made coring continental margins, drift deposits, and basins where high sedimentation rates (1 m ka⁻¹) and/or low sediment mixing allow rapid changes in climate and ocean circulation to be resolved.

The effect of bioturbation (mixing by worms and other organisms at the seafloor) is an important consideration in higher resolution studies of climate change. Bioturbation can thoroughly mix 10 cm of sediment (equivalent to 1000–2000 years at typical sedimentation rates) before the sediment is buried below the reach of benthic organisms. Bioturbation is sometimes evident by mottled coloring of sediments, as seen in core photographs ([Figure 1](#)). The smoothing effect is greatest when the rate of change is fast, the change is large, and the sedimentation rate is low. Milankovitch cycles (100–23-ka period) are readily preserved at typical deep sea sedimentation rates, while millennial-scale cycles are often attenuated. To minimize the effects of bioturbation, studies have exploited high sedimentation rate cores or cores from anoxic marine basins where benthic activity is minimal. Under the highest sedimentation rates, in the absence of sediment mixing, finely sampled marine cores appear capable of resolving events occurring within a few years or even a single year.

Oxygen Isotope Stratigraphy

Beyond the limit of radiocarbon (approximately 40000 years BP), the stratigraphic framework for the study of the Quaternary in marine sediment cores has been derived by measuring the oxygen isotope ratio in marine carbonates (see [Oxygen-](#)

[Isotope Stratigraphy of the Oceans](#)). Two stable isotopes of oxygen exist, ¹⁸O and ¹⁶O, and their ratio in marine carbonates varies according to the ratio in seawater and the temperature at which the carbonate is secreted. The seawater ¹⁸O/¹⁶O ratio is sensitive to climate and particularly to the amount of ice stored in continental ice sheets. Oxygen isotope variations found in marine sediments are thus related to climate, and the variations through time are dominated by cycles that can be correlated with the orbital cycles in solar radiation. The orbital cycles in solar radiation can be calculated with high accuracy independently of the sediment record (see [Astronomical Theory of Paleoclimates](#)). The offset between the orbital cycles and the oxygen isotope record can be determined empirically from sediment cores by radiocarbon dating the last 30000 years and from U–Th dating of the coral terraces that indicate sea level maxima (and oxygen isotope minima) during marine isotope stages 3, 5, and 7 ([Imbrie et al., 1984](#)). The offset can alternately be determined from a model of ice sheet growth ([Lisiecki and Raymo, 2005](#)). Using this offset, a chronology for the oxygen isotope series (usually a composite (stacked) record of oxygen isotope variations) can be developed by aligning the oxygen isotope record to the orbital variations. In practice, chronologies for new cores are produced by aligning an oxygen isotope record to a stacked $\delta^{18}\text{O}$ time series, such as the one produced by [Lisiecki and Raymo \(2005\)](#). The orbital tuning approach using stacked oxygen isotope records has now been extended back more than 5.3 Ma, providing numbered isotope events and a chronology with uncertainty of 6000 years or less for the Quaternary.

Proxies

Over the past four decades, paleoceanographers have developed an extensive array of proxies of past climate and environment ([Table 1](#)), developed principally from proxies found in whole sediment and from the geochemical composition of plankton shells such as the calcium carbonate skeleton of the foraminifer *Globigerina bulloides* ([Figure 2](#)). The attributes of foraminifer shells make them ideally suited to record environmental information. Planktonic foraminifers inhabit and record variations in the sea surface environment (with possible species-specific seasonal and depth habitats; see [Planktic Foraminifera](#)), while benthic foraminifers record the environment at the seafloor or within the uppermost sediment layers (see [Benthic Foraminifera](#)). Foraminifer shells are composed

of calcium carbonate (CaCO_3), incorporating the isotopes of oxygen and carbon, and the element calcium, as well as trace metals that substitute for calcium or become incorporated into the calcite lattice. Almost all proxies are subject to multiple influences, and while the relationship between oxygen isotope ratios in modern specimens and modern ocean temperatures can be constrained, the possibility remains that other influences have affected the proxy in the past. Oxygen isotopes, influenced both by the isotopic composition of the water and by the temperature at which the calcite is precipitated, are a well-known example of a proxy that is subject to multiple influences. For this reason, paleoceanographic data are almost always presented in their original units (e.g., $\delta^{18}\text{O}$ -calcite), accompanied by an interpretation in terms of the dominant influence(s) (temperature or $\delta^{18}\text{O}$ -water in the case of $\delta^{18}\text{O}$ -calcite). Constraining the other influences using additional proxies or by measuring more than one proxy for the same

environmental variable remains a preferred strategy in interpreting paleoceanographic records. The recent application of Mg-/Ca-based paleothermometry measured on the same shells where oxygen isotopes have been measured is a notable success in constraining the influence of temperature on the oxygen isotopic composition and enables the reconstruction of the two most important variables in physical oceanography: temperature and salinity (see [Oxygen Isotope Composition of Seawater, Salinity Proxies \$\delta^{18}\text{O}\$](#)). The use of radioisotopes to constrain accumulation rates shows promise in the reconstruction of sediment fluxes (see [Radioisotope Proxies](#)). Paleoceanographic proxies and their interpretation are discussed in articles listed in [Table 1](#).

Evolution During the Quaternary

Proxy records, such as benthic and planktonic foraminiferal oxygen isotopes and ice-rafted debris from high latitudes, have expanded our understanding of the evolution of climate during the Quaternary. A distinctive feature is the onset of the Quaternary Ice Ages as well as the progressive cooling of the high latitude sea surface and the deep ocean ([Lisiecki and Raymo, 2005](#)). In contrast, records from low latitudes indicate that the sea surface temperature (SST) of the tropical warm pool regions remained stable during the last 5 Ma. The result is a dramatic increase in the zonal (west–east) and meridional (north–south) gradients in SST, accompanied by a progressive cooling of the water upwelled along the eastern margins of the Pacific (Peru, California) and South Atlantic (Africa).

Zonal and Meridional Gradients in SST

A notable feature of SST reconstructions is the emergence of the modern equatorial Pacific cold tongue and changes in upwelling during the mid-Pleistocene. A comparison of SST between the western and eastern equatorial Pacific shows that there is a

Figure 1 Piston core V18-68 from the Southeast Pacific (55°S , 78°E), split into two halves. This core is comprised of foraminifer ooze (a mixture of clay and plankton remains that include the calcium carbonate skeletons of foraminifers and coccoliths). The mottling and color variations in this section (350–370 cm) are the result of mixing of sediment by organisms that occurred at the seafloor prior to the accumulation of additional sediment (from the Index to Geological Samples, <http://www.ngdc.noaa.gov/mgg/>).

Table 1 Paleoceanographic proxies for climate and environmental change

Proxy	Climate/environmental significance	Article
Mg/Ca, Sr/Ca	Sea surface temperature	Mg/Ca and Sr/Ca Paleothermometry from Calcareous Marine Fossils
Alkenone saturation (U^k_{37})	Sea surface temperature	Alkenone Paleothermometry Based on the Haptophyte Algae; Biomarker Indicators of Past Climate
Fossil plankton census counts	Sea surface temperature	Temperature Proxies, Census Counts
$\delta^{13}\text{C}$, Cd/Ca, Ba, Zn/Ca, $\delta^{15}\text{N}$	Nutrients, ocean circulation, and ocean ventilation	Nutrient Proxies; Carbon Cycle Proxies ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, Shell Weights, B/Ca, U/Ca, Zn/Ca, Ba/Ca)
$\delta^{18}\text{O}$	Ice volume, ocean temperature	Oxygen-Isotope Stratigraphy of the Oceans; Oxygen Isotope Composition of Seawater; Salinity Proxies $\delta^{18}\text{O}$
CaCO_3	Plankton production, dissolution, carbon cycle	Dissolution of Deep-Sea Carbonates
Tex_{86}	Temperature	Biomarker Indicators of Past Climate
HBI (highly branched isoprenoid alkenes)	Temperature	Biomarker Indicators of Past Climate
Lipid δD	Salinity	Biomarker Indicators of Past Climate
$\delta^{11}\text{B}$, $\delta^{13}\text{C}$ -calcite, $\delta^{13}\text{C}$ -organic, shell weight, U/Ca, Li/Ca, Cd/Ca, Zn/Ca, Ba/Ca	Carbon cycle	Carbon Cycle Proxies ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, Shell Weights, B/Ca, U/Ca, Zn/Ca, Ba/Ca)
^{230}Th , ^{231}Pa	Sediment accumulation, ocean circulation	Radioisotope Proxies

notable increase (~ 3.5 to $\sim 5^\circ\text{C}$) in the equatorial Pacific zonal SST gradient during the interval between 1.2 and 0.8 million years (My) ago (Figure 3). Liu and Herbert (2004) reported decreasing alkenone-derived SSTs from a record from the eastern equatorial Pacific for the last 1.8 My. In contrast, SSTs in the western Pacific warm pool (WPWP) remained relatively stable throughout the Pleistocene epoch (Degardel-Thoron et al., 2005). Oxygen isotopes, alkenones, and Mg/Ca measurements from the western and eastern equatorial Pacific show that there appear to be permanent El-Niño-like conditions during the Pliocene warm period (Dekens et al., 2004; Wara et al., 2005). During the warm early Pliocene (4.5–3.0 Ma), the eastern Pacific thermocline was deep and the west-to-east

SST difference across the equatorial Pacific was relatively small ($1.5 \pm 0.9^\circ\text{C}$), much like a modern El Niño event. After 1.7 Ma, however, SST in the eastern equatorial Pacific began decreasing, while the SST in the western equatorial Pacific remained warm. Hence, the zonal SST difference increased up to $4\text{--}5^\circ\text{C}$ at 1.7 Ma. Meanwhile, SSTs cooled in middle-latitude eastern margin boundary upwelling regions (California, Peru, Africa), increasing the north–south temperature gradient (Dekens et al., 2004; Federov et al., 2006; Marlow et al., 2000). The data reveal that the meridional temperature gradient increased from $\sim 2^\circ\text{C}$ to $\sim 8^\circ\text{C}$, indicating a vastly poleward expansion of the tropical ocean warm pool at that time. Federov et al. and Dekens et al. hypothesize that both the zonal and meridional gradients were accompanied by steepening of the vertical temperature gradient in the ocean, a hypothesis supported by the analysis of surface and deep-dwelling Foraminifera (Wara et al., 2005). Both of these changes likely contributed to the increased sensitivity to orbital forcing that marked the mid-Pleistocene transition (Figure 4).

Figure 2 Calcium carbonate shell of *Globigerina bulloides* from a sediment trap sample collected in the Santa Barbara Basin in the eastern Pacific (photograph by Robert Fisher, University of Colorado).

Mid-Pleistocene Transition

There have been several hypotheses regarding the mid-Pleistocene climate change. Medina-Elizalde and Lea (2005) investigated the SST record from a site in the western equatorial Pacific warm pool based on planktonic foraminiferal magnesium/calcium ratios. They focused on the timing and nature of tropical Pacific SST changes over the mid-Pleistocene transition, and showed that SST changes in the western equatorial Pacific warm pool were synchronous with eastern Pacific cold-tongue SST, but preceded changes in continental ice volume. Based on the records, they considered changes in atmospheric carbon dioxide as the cause of the switch in climate periodicities at this time. Herbert et al. (2010) also emphasized the

Figure 3 Top: Evolution of the Pacific West–East sea surface temperature gradient during the past 4 Ma based on Mg/Ca (red, from ODP 806 in the western equatorial Pacific) and Mg/Ca (blue) and alkenones (green dots) in the eastern equatorial Pacific (ODP 847). Larger circles are additional Mg/Ca data for ODP 806 (red) and 847 (blue). Bottom: Progressive cooling of coastal upwelling regions revealed by alkenone records from Peru (blue, ODP 1237), California Margin (black, ODP 1014), and the West African Margin (green, ODP 1084). Modified from Federov AV, Dekens PS, Mccarthy MD, et al. (2006) The Pliocene paradox (mechanisms for a permanent El Niño). *Science* 312: 1485–1489.

Figure 4 Time series and wavelet analysis of June solar radiation at 65° N (Berger and Loutre, 1991) (W m^{-2}) (right) and oxygen isotope variations (Lisiecki and Raymo, 2005) (per mil) for the past 1.6 million years (left). Increasing ice volume and/or cooling is upward in this figure. The wavelet spectrum (bottom panels) reveals the variance at the orbital frequencies of eccentricity (100 000 years), obliquity (41 000 years), and precession (23 000 years) and shows the increase in 100 000-year variance between 1 and 0.65 Ma that characterized the mid-Pleistocene transition.

importance of determining the timing and amplitude of tropical SST in solving the puzzle of the Plio–Pleistocene. According to them, alkenone-based tropical SST records from the major ocean basins show coherent Glacial–Interglacial temperature changes that align with global changes in ice volume and deep ocean temperature over the past 3.5 My. They pointed out that tropical temperatures became tightly coupled with benthic $\delta^{18}\text{O}$ and orbital forcing after 2.7 Ma, suggesting that the inception of a strong carbon-dioxide-greenhouse-gas feedback and amplification of orbital forcing at 2.7 Ma corresponded to the onset of Northern Hemisphere glaciation.

Others, however, challenge the hypothesis of a gradual decrease in atmospheric CO_2 concentration as a dominant trigger of the larger 100-ka glacial cycles since 850 000 years BP. According to Degardel-Thoron et al. (2005), the mid-Pleistocene cooling was restricted to upwelling regions, whereas surface temperatures remained at the same mean level before and after 0.8 Ma in the WPWP. They suggest an alternative hypothesis that nonlinear, coupled ocean-atmosphere dynamics regulate the equatorial Pacific climate. The increased temperature contrast between the eastern equatorial Pacific upwelling regions and the thermally stable WPWP in the mid-Pleistocene probably led to the intensification of the Walker circulation. This strengthening of the zonal Pacific atmospheric circulation is further supported by the surface freshening of the WPWP. These changes might have led to atmospheric processes and oceanic interactions which could have altered the meridional heat and moisture transfers to the Northern Hemisphere ice sheets during the mid-Pleistocene transition and thus contributed to Northern Hemisphere glaciations.

The meridional expansion of the tropical warm pool during the warm Pliocene period evidently had enormous impacts on the Pliocene climate, including a slowdown of the atmospheric Hadley circulation and El-Niño-like conditions in the equatorial region. On the other hand, the atmospheric response to the

reduced zonal SST gradient indicates relatively weak zonal Walker circulation. The mechanisms of ocean heat uptake, such as enhanced ocean vertical mixing, were also considered to play a role in sustaining a climate state with a weak tropical SST gradient. A positive feedback between hurricanes and the upper-ocean circulation in the tropical Pacific Ocean may have been essential for maintaining warm, El-Niño-like conditions during the early Pliocene (Fedorov et al., 2010). More frequent and/or stronger hurricanes in the central Pacific imply greater heating of water parcels, warmer temperatures in the eastern equatorial Pacific, warmer tropics, and in turn, even more hurricanes. The increase in meridional and zonal SST gradients in the Pacific during the mid-Pleistocene implies a change in the mean climate state from El-Niño-like state to more La-Niña-like condition, which implies an intensification of the Walker circulation during the mid-Pleistocene.

Glacial–Interglacial Cycles

Paleoceanographic records provide a valuable complement to terrestrial evidence of the Quaternary Glacial–Interglacial cycles. Continuous in time and widespread in geographic distribution, paleoceanographic records provide a way of understanding how the climate system changes during glacial cycles. The following discussion emphasizes the changes that occurred during the Last Glacial Maximum (LGM), 21 000 calendar years BP, recognizing that previous glacial cycles of the last 850 000 years share many of the same characteristics. Two aspects of the glacial world are particularly significant: (1) the large sensitivity of the North Atlantic region compared to other regions (glacial changes were larger here than anywhere else), and (2) the similarity between temperature and atmospheric carbon dioxide change (and changes in carbon in the ocean),

clearly implicating the role of carbon dioxide as an amplifying influence on the glacial–interglacial cycles.

Climate Sensitivity of the North Atlantic Compared to Other Regions

Since the pioneering CLIMAP (Climate: Long-Range Investigation Mapping and Prediction) studies (CLIMAP Project Members, 1981), many efforts have been made to map SST changes that occurred between the present and the LGM, 21 000 years BP. While the earliest widespread compilations were based on faunal assemblages, later studies have used oxygen isotopes, alkenones, Mg/Ca, and other proxies (Waelbroeck et al., 2009). All approaches are consistent in showing that large cooling occurred in the North Atlantic compared to other regions. Comparing alkenone-based estimates (Rosell-Mele et al., 2004) with the original CLIMAP estimates (the latter expressed as annual mean zonal averages; Shin et al., 2003) for the LGM, the North Atlantic (40–60° N) was 7–8 °C colder than present, compared to a cooling of up to 5 °C in the North Pacific and 4 °C in the southeastern Atlantic. Higher latitude regions (>60°) that are close to freezing today cooled less, forming sea ice instead. The tropical oceans were a few degrees colder (Table 2). The least amount of cooling occurred in the subtropical gyres. Based on these reconstructions, the North Atlantic appears to be about 2–3 times more sensitive than the low latitude oceans due to a combination of factors that include the growth of ice on the surrounding continents, changes in sea ice extent, and changes in ocean circulation. The original CLIMAP studies showed some regions within several of the subtropical gyres to be warmer than present at the LGM. Some subsequent studies have supported this result, while others have indicated that the subtropical gyres were no different or slightly cooler than today (Waelbroeck et al., 2009). All the studies indicate that the gyres are remarkably insensitive to change compared to other regions.

Changes in the meridional overturning circulation could contribute to the large climate sensitivity of the North Atlantic, provide a link between ice sheets and ocean circulation, and influence global climate as well. The decrease in deep water formation results in a much colder surface waters in the North Atlantic, with widespread effects across the Northern Hemisphere. The meridional overturning circulation has been interpreted from different tracers. The most extensive reconstruction uses $\delta^{13}\text{C}$ and Cd/Ca to produce a glacial section that can

be compared to the modern GEOSECS $\delta^{13}\text{C}$ and phosphate measurements (Curry and Oppo, 2005; Lynch-Stieglitz et al., 2007) (Figure 5). The glacial section reveals three different end-member water masses: (1) a shallow (1000 m) southern-source water mass (2), a mid-depth (1500 m) northern-source water mass (3), and a deep (>2000 m) southern-source water mass. Similar to previous compilations and studies based on other proxies, the section shows reduced southward penetration of the northern-source water mass corresponding to present-day NADW and the increased northward penetration of the deepest, southern-source water mass. The $\delta^{13}\text{C}$ of the intermediate depth is enriched relative to modern, consistent with a more shallow overturning circulation, forming a water mass that has been called Glacial North Atlantic Intermediate Water. Proxies for the rate of circulation (^{14}C , $^{231}\text{Pa}/^{230}\text{Th}$) indicate the glacial deep circulation was not much slower than today. A key unresolved aspect of the overturning circulation, relevant to the glacial state, millennial-scale variability, and future change, is whether different stable modes exist (Hofmann and Rahmstorf, 2009).

Role of the Ocean in Carbon Dioxide and Climate Change

One of the most significant findings with regard to future climate change is the observed correlation between changing temperature and carbon dioxide concentrations in the atmosphere. By comparing the magnitude of glacial to interglacial temperature change with the magnitude of carbon dioxide change, it is possible to independently confirm the climate sensitivity: the amount of change that might be expected in the future due to emissions of carbon dioxide from the burning of fossil fuels. While ice cores provide this correlation, paleoceanographic proxies can also be used to make this comparison, employing proxies for temperature and carbon in the surface ocean.

In addition to helping calibrate the sensitivity to carbon dioxide, paleoceanographic records are also useful in understanding the ocean's role in the carbon cycle. The ocean contains sixty times more carbon than the atmosphere due to its large volume and the ability of carbon dioxide to chemically react in seawater to form carbonic acid (H_2CO_3), carbonate (CO_3^{2-}), and bicarbonate (HCO_3^-) ions (see Dissolution of Deep-Sea Carbonates). Most of this carbon resides in the deep sea, kept out of the surface ocean by the continuous formation and sinking of fixed carbon by biological activity (termed the biological pump), and the slow return to the surface by ocean circulation. One of the first-developed proxies for the biological pump was the difference in the carbon isotope ratio $\delta^{13}\text{C}$ recorded in planktic and benthic foraminifers ($\Delta\delta^{13}\text{C}$) (Shackleton et al., 1983). The surface ocean is high in $\delta^{13}\text{C}$ because ^{12}C is preferentially removed as fixed carbon, and the deep ocean is low in $\delta^{13}\text{C}$ because the fixed carbon with low $\delta^{13}\text{C}$ is later added to the deep sea by respiration and regeneration (see Carbon Cycle Proxies ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, Shell Weights, B/Ca, U/Ca, Zn/Ca, Ba/Ca)). Comparison of SST derived from Mg/Ca in the western tropical Pacific (Degaridel-Thoron et al., 2005) with the record of $\Delta\delta^{13}\text{C}$ from a Pacific core reveals that the carbon isotope gradient is larger during glacial times when the SST is cooler, and the gradient is smaller during interglacial times when the temperature is warmer (Figure 6). More light carbon was in the deep sea, and less in the surface

Table 2 Change in sea surface temperature (°C) between the Last Glacial Maximum and the present based on the alkenone proxy and faunal changes (CLIMAP)

Region	Difference from modern (alkenones)	Difference from modern (CLIMAP annual zonal mean)
Northeast Atlantic (30–45° N)	Up to –7	–8
Northeast Pacific (40–60° N)	Up to –5	–2
Tropical Pacific	–2.0	–1
Tropical Atlantic	–2.7	–2
Tropical Indian	–1.7	–2
Southeastern Atlantic	Up to –4	–2 to –3

Figure 5 North Atlantic Deep Water production during the Last Glacial Maximum (LGM). Reproduced/modified from Curry WB and Oppo DW (2005) Glacial water mass geometry and the distribution of $\delta^{13}\text{C}$ of total CO_2 in the western Atlantic Ocean. *Paleoceanography* 20: PA1017, with permission of American Geophysical Union.

ocean, during glacial times. These changes in the carbon isotope gradient can be scaled to provide a record of atmospheric carbon dioxide. More recently developed evidence from boron isotopes confirms the reduction in dissolved carbon dioxide in the surface ocean during glacial times (Hoenisch et al., 2009) and also reveals the stability of carbon dioxide since at least 2.1 Ma.

Millennial-Scale Variability During Glacial Times

In addition to the Quaternary glacial cycles found in all marine sediment cores, some paleoceanographic records contain finer-scale variations that are largest during glacial times, such as the interval from 60 000 to 20 000 years BP (see [Sub-Milankovitch \(DO/Heinrich\) Events](#)). Two different types of millennial-scale variability are observed during the last

glacial interval. Dansgaard-Oeschger (D-O) events describe a series of warm (interstadial) and cool (stadial) events that are recorded in the oxygen isotopes of Greenland ice cores. Twenty-five events are numbered during the last glacial interval, each lasting from 600 to 2000 years and each characterized by progressive cooling followed by abrupt warming. Heinrich (H) events are other millennial-scale events that occurred during the last glacial. Heinrich events were initially defined on the basis of coarse sediments found in discrete layers in North Atlantic sediments and represent times when coarse ice-rafted material was transported farther south. Six events have been widely identified in North Atlantic sediments (H1, 14 300; H2, 21 000; H3, 27 000; H4, 35 500; H5, 52 000; and H6, 69 000 years BP), each occurring at the coldest part of a D-O cycle. The Younger Dryas shares some similarities with both D-O stadial events and H events, and can be considered the last H event

Figure 6 Paleoceanographic records reveal the covariation between carbon gradients (Shackleton et al., 1983) and sea surface temperature (Degaridel-Thoron et al., 2005) in the western Pacific warm pool. The vertical gradient in $\delta^{13}\text{C}$ was one of the first of many paleoceanographic proxies that record the partitioning of carbon between the surface and deep ocean, revealing the ocean's role in determining the Ice Age variations in atmospheric carbon dioxide.

(H0, 11 000 years BP) on the basis of cold, fresh conditions found in the North Atlantic. Subsequent studies have also shown that the H events are characterized by colder SSTs, in addition to extensive ice-rafting, and by a freshwater anomaly further north, as indicated by $\delta^{18}\text{O}$ records. One of the early records of millennial-scale cooling of the North Atlantic, sea surface is found in increasing percentages of *Neogloboquadrina pachyderma* left-coiling (Figure 7(b); Bond et al., 1992).

While the amplitude of SST changes and the episodic ice-rafting events are largest and best documented in the North Atlantic, paleoceanographic records show evidence of millennial-scale variability far from the North Atlantic (Voelker et al., 2002). The extent of millennial-scale variability outside the North Atlantic and the climate processes involved are the subject of intense research and remain limited by less certain dating beyond the range of radiocarbon dating (40 000 years BP) and also by bioturbation (see Introduction) that attenuates millennial-scale variability. Two regions where appropriate sediments exist are the Santa Barbara Basin off California (Site 893) and the Oman Margin in the Arabian Sea (RC2714). Both regions are characterized by high sedimentation rates ($>25 \text{ cm ka}^{-1}$) and low oxygen concentrations at the seafloor. Both sites record millennial-scale events during the past 50 000 years, indicative of increased ventilation and/or reduced productivity during cool periods in Santa Barbara Basin (Figure 7(c); Cannariato and Kennett, 1999), and indicative of decreasing denitrification and/or reduced productivity along the Oman Margin during cool periods (Figure 7(d); Altabet et al., 2002). Several different mechanisms have been proposed to explain the link between the North Atlantic and these remote sites, some involving atmospheric circulation (both sites are characterized by strong wind-driven upwelling today), and another group of

explanations tied to global changes in the ventilation of the upper intermediate ocean.

While the preceding discussion examines the millennial-scale variability during the last glacial interval, from 120 000 to 10 000 years BP, longer records show that millennial-scale variability was a persistent feature of at least the preceding four glacial cycles (the last 500 000 years), prevalent whenever benthic $\delta^{18}\text{O}$ exceeded 3.5 per mil (McManus et al., 1999). These oscillations and events are absent or much reduced during the postglacial interval. The presence of this variability only during glacial times, the abrupt, sawtooth character of the cycles, and the long time between events (thousands of years) have led to many explanations that involve the interaction between ice sheet growth and decay, the surface and deep circulation in the North Atlantic, and the bipolar seesaw (Barker et al., 2011).

The Last Deglaciation

Regional differences in the timing and the pattern of deglaciation provide important evidence regarding the mechanisms driving the Earth's glacial cycles. Unfortunately, age uncertainty in marine sediments still makes it difficult to evaluate the events and rapid changes that occurred during the deglaciation that differ by only several hundred years. While the measurement uncertainty of radiocarbon (one standard deviation) during this time interval is on the order of 50 years, the practical uncertainty due to changes in reservoir age, bioturbation, and other effects is on the order of several hundred years. This uncertainty makes it extremely difficult to determine the alignment of Younger Dryas cooling observed in ice cores with sea level determined from

Figure 7 Paleoceanographic records of millennial-scale variability compared to the GISP 2 oxygen isotope record (a) (Grootes et al., 1993) includes *N. pachyderma* (left-coiling) abundance in the North Atlantic (greater abundance indicates cooler sea surface temperature) (c) (Bond et al., 1992), the percent of disoxic foraminifers in Santa Barbara Basin Site 893 (increasing percentages indicate greater ventilation or reduced productivity) (b) (Cannariato and Kennett, 1999), and the $\delta^{15}\text{N}$ ratio in core RC2714 from the Arabian Sea (higher $\delta^{15}\text{N}$ indicates higher nutrient utilization, a measure of increased productivity) (d) (Altabet et al., 2002).

corals, SSTs, and meltwater events observed in oxygen isotope records. Despite this uncertainty, two different broadscale patterns of the last deglaciation can be observed, upon which, regional differences are superimposed. One pattern is typical of the North Atlantic region and is characterized by a rapid change from full glacial conditions beginning 15 ka (Figure 8; Lea et al., 2003). The abrupt change toward interglacial conditions was interrupted by a brief return to almost full glacial conditions during the Younger Dryas interval (13 000–11 700 years BP). The Younger Dryas interval ended with an abrupt transition toward the present interglacial. This pattern typifies most North Atlantic records and is also found in regions far from the North Atlantic, such as the California Margin and the Asian Monsoon region (Figure 7). Records that show large

millennial-scale variability also tend to show the abrupt pattern during the deglaciation.

In contrast, sediments from western tropical Pacific and high southern latitudes are characterized by a different pattern that begins earlier (17 000 years BP) and warms more gradually (Figure 8; Stott et al., 2007; Visser et al., 2003). This pattern also contains a brief return toward colder conditions, but the reversal is not as large and the timing is different from the Younger Dryas, beginning around 15 000 years BP. The sequence of events during the last termination remains an active research topic. Hypotheses regarding mechanisms can be divided into those that emphasize changes in the tropics, high southern latitudes (Anderson et al., 2009) and possibly southern insolation, and those that emphasize initiation by increased northern

Figure 8 Temperature change during the last deglaciation revealed by alkenone-based reconstructions of sea surface temperature in the tropical Pacific (red) and tropical Atlantic (blue) (Stott et al., 2007; Visser et al., 2003).

seasonality (65° N) (Clark et al., 2009), with a possible role of the Asian monsoon and the intertropical convergence zone (ITCZ) (Cheng et al., 2010). More information on the last deglaciation, including its regional characteristics, is provided in the individual articles.

Postglacial

The largest external influence on Holocene climate was the 8% decrease in summer radiation (and increase in winter radiation) that occurred between 11,000 years BP and the present due to the precession of the Earth's axis of rotation. Summers were warmer and winters colder over the Northern Hemisphere 11,000 years ago, a contrast that is much reduced today. These changes are expected to have caused stronger monsoon circulation 11,000 years BP, and the strengthening of the monsoon in the early Holocene observed in both data and model simulations is one of the successes of Quaternary paleoclimatology (see [Postglacial Indian Ocean](#)).

New proxies have refined our understanding of other climate changes during the postglacial. In the tropics, the ITCZ appears to have been located northward of its present mean position during the early Holocene and appears to have moved south during the Holocene. In the African and Asian sectors, this would have contributed to weakening the monsoon circulation. In the Atlantic, the southward migration of the ITCZ has been documented by decreasing Ti and Fe concentrations in Cariaco Basin sediments, an indicator of decreasing rainfall over the adjacent continent that is best explained by southward movement of the

ITCZ during the Holocene (Haug et al., 2001) (see [Postglacial North Atlantic](#)). In the Pacific, the east–west SST gradient, indicative of the strength of the Walker circulation, was largest during the mid-Holocene, reduced today, and much reduced during the last glacial interval (Koutavis et al., 2002; see [Postglacial North Pacific](#), [Postglacial South Pacific](#)). These changes support the hypothesis of an El-Niño-like mean state in the Pacific during the last glacial interval, and more La-Niña-like mean conditions during the middle Holocene. Progressive freshening of the western Pacific sea surface from the beginning to the end of the Holocene is supported by the oxygen isotope record in the western Pacific, after removal of the temperature effect using Mg/Ca (Stott et al., 2004).

An intriguing aspect of paleoceanographic records of the postglacial interval is the evidence for small-amplitude century-scale cycles that correlate with records of solar variability derived from ^{10}Be and ^{14}C variations. First observed in records of ice-rafting in the North Atlantic (Bond et al., 2001), millennial-scale variability has also been observed in paleoceanographic records of the Asian summer monsoon (Fleitmann et al., 2003; Gupta et al., 2003). Unlike the Milankovitch changes in summer insolation that are large (8%), these changes in (total annual) radiation are small (less than 1%), requiring amplifying mechanisms not yet understood. The changes observed in paleoceanographic records are so small that the changes are close to the uncertainty in most proxies and perhaps only detectable in regions where the changes are unusually large. Some consider the Medieval Warm Period, the Little Ice Age, and part of the warming since the Little Ice Age (during the last century) to be the most recent

manifestations of the solar cycles. The societal relevance of this aspect of natural climate variability warrants further research, where paleoceanographic records have great potential.

Introduction

In paleoceanography, the term ‘alkenones’ refers to a series of C₃₇–C₃₉ straight-chain methyl and ethyl ketones with one to four unsaturations and all-*trans* configuration in the double bonds (Figure 1). Besides this group of compounds, there are homologues (compounds with similar general chemical formula due to the presence of the same functional group but differs in their molecular mass by a CH₂ group) of shorter or longer alkyl chains, but to date, these additional ketones are of very limited paleoceanographic interest. The alkenones have been found in recent marine sediments of widespread geographical locations from the tropics to the subpolar regions and in marine sediment as old as the Cretaceous (Brassell and Dumitrescu, 2004).

Since their first reported occurrence in the sediment from the Walvis Ridge (Boon et al., 1978) and subsequent identification (de Leeuw et al., 1980), the alkenones have been intensively studied, especially the C₃₇ di- and triunsaturated homologues. Over the years, these biomarkers have shown to be a remarkably robust organic molecular sea surface temperature (SST) proxy in the form of the alkenone unsaturation index (see review by Herbert et al., 2003) and have allowed the description of the SST variability on various timescales in the global ocean throughout the late Cenozoic, ranging from the Pliocene (e.g., Herbert et al., 2010; Lawrence et al., 2006) and the Pleistocene (e.g., Lamy et al., 2004; Martínez-García et al., 2009; Martrat et al., 2007) to shorter timescales such as centennial (Eglinton et al., 1992), decadal (Sicre et al., 2008), or even as short as interannual changes (Kennedy and

Brassell, 1992). It has also been shown to be able to register abrupt climatic changes, such as Dansgaard–Oeschger cycles (Cacho et al., 1999; Harada et al., 2006). To date, the alkenones are probably the best biomarker for SST reconstruction. They offer several advantages over the classical proxies based on carbonate microfossils. For instance, the alkenone unsaturation index is found to be unaffected by carbonate dissolution (Sikes et al., 1991), making it applicable for sediments found beneath the calcium compensation depth which are barren of carbonate tests. It also provides an opportunity for SST reconstruction in regions where the diversity of microfossil taxa is too low for a successful assemblage transfer-function-based SST reconstruction. Within the past two decades, the alkenone unsaturation index has become one of the most widely used SST proxies in the world. Interlaboratory results can easily be compared as the maximum difference between any two laboratories for the alkenone-derived SST on the same samples is less than 2.1 °C (with a probability of 95%) (Rosell-Melé et al., 2001).

Quantification and Analytical Challenges

One of the advantages of using the C₃₇ alkenones for paleoceanographic studies is that the laboratory protocols involved in obtaining and quantifying these biomarkers are relatively simple and straightforward. Work by Sikes et al. (1991) demonstrated that the alkenone unsaturation index is not affected by the condition of storage (at room temperature or frozen) for up to several years. This finding has great implications for the general applicability of this proxy, that is, it could be applied on marine sediments that were retrieved several decades ago

Figure 1 Chemical structures of the C_{37} alkenones, which are of main interest for paleoceanographic studies.

and might not have been kept frozen since their retrieval. Moreover, although there are cases where the plastic sample bags were found to contaminate the sediment by introducing a compound that coelutes with the $C_{37:3}$ alkenone (Sachs and Lehman, 1999), storing the sediment cores in plastic liners does not generally seem to hinder alkenone analysis.

Prior to analysis, the extractable organic matter (of which the alkenones are part) are obtained from bulk sediment samples, either by microwave-assisted extraction, by repeated sonication, by Soxhlet apparatus, or by an accelerated solvent extractor system. Additional sample clean-up procedures, such as saponification, silica gel chromatography, or urea adduction may be necessary if the sample has high organic matter content, or there are compounds that coelute with the alkenones during analysis.

Gas chromatography coupled with a flame ionization detector (GC-FID) is the most widely used method for alkenone analysis. The GC is equipped with a long nonpolar column coated with chemical film to enhance separation. Along with the implementation of a slow high-temperature program, this enables the alkenones to be separated from other compounds and subsequently quantified by the FID. The commonly used column length is between 30 and 60 m. The longer the column, the better the separation of alkenones in the chromatograms. Although FID is a sensitive detector, it does not provide information about the chemical structure of the compounds. In a GC-FID system, identification of alkenones is achieved principally by the comparison of their elution time with that of external standards. Therefore, it is strongly recommended to run duplicates of the samples on another system that could provide extra information about the chemical structure of measured compounds, such as a gas chromatography coupled with mass spectrometry (GC-MS), to confirm the alkenone identification and to ensure that the alkenone-derived SST estimates are not biased by coeluting compounds. Recently, a novel approach based on a fast GC/time-of-flight mass spectrometry was proposed by Hefter (2008) as an alternative for alkenone identification done with the conventional GC-FID system. This approach could reduce the analysis time by a factor of 10 and circumvent the bias introduced by coelution that may not be detected in a GC-FID, in addition to yielding a higher sensitivity compared to a conventional GC-MS.

Apart from the bias caused by coeluting compounds, the accuracy in the estimation of paleotemperatures might also be compromised at low alkenone abundances. Irreversible

adsorption of a portion of the alkenones, preferentially $C_{37:3}$ alkenone into the chromatographic column, poses one of the potential challenges (Grimalt et al., 2001; Villanueva and Grimalt, 1997). This problem could be amplified at the high-temperature end of the unsaturation index scale where the $C_{37:3}$ alkenone is in low abundance, resulting in spuriously warm SST estimates. One plausible way of circumventing this problem is via long-term monitoring of the GC system by running reference standards with a known alkenone unsaturation index.

Chemical Structures

The chemical structure of alkenones was first elucidated by de Leeuw et al. (1980). They found that alkenones have several unusual characteristics for biolipids, in terms of their chain length (C_{37-39}) and the spacing of the unsaturation (C7 instead of the more common C2 or C3). The C_{37} alkenones in marine sediments could be di-, tri-, and tetraunsaturated. The synthesis of these alkenones in both all-*cis* and all-*trans* configurations and coinjection with natural samples allows determination that the double bonds in alkenones have the rare all-*trans* configuration (Rechka and Maxwell, 1988) as opposed to the more common *cis* configuration, that is, (*E,E*)-15,22-heptatriacontadien-2-one ($\text{Me}_{37:2}$), (*E,E,E*)-8,15,22-heptatriacontatrien-2-one ($\text{Me}_{37:3}$), and (*E,E,E,E*)-8,15,22,29-heptatriacontatetraen-2-one ($\text{Me}_{37:4}$). These compounds are also widely known as $C_{37:2}$, $C_{37:3}$, and $C_{37:4}$ alkenones or ketones in the literature. In general, GC-MS is the technique of choice for structural characterization of the alkenones, since it has enough sensitivity, based on the fragmentation pattern of the molecules, to detect their presence in sediments, algae, or waters where they are often found in low concentrations.

The alkenone distributions so far identified could be grouped arbitrarily in two types (tentatively named type A and type B for convenience of discussion). Type A consists of C_{37} methylketones, C_{38} methyl and ethylketones, C_{39} methyl and ethylketones, and C_{40} ethylketones (Figure 2). Alkenones with this distribution are synthesized by several haptophyte algae such as coccolithophorids *Emiliania huxleyi* (Figure 3), *Gephyrocapsa oceanica*, and several strains of the species *Isochrysis* (Marlowe et al., 1990) found in marine waters and sediments and in a few nonmarine environments (Figure 4). On the other hand, the only known algal precursor of the less

Figure 2 Gas chromatograms using GC-FID, showing examples of the two types of distributions of the C_{37} – C_{40} alkenones. Full chemical names of the compounds are given in [Table 1](#).

Figure 3 Coccoliths of *Emiliana huxleyi*, at present the main alkenone producer in the global ocean.

common type B distribution is *Chrysotila lamellosa* ([Rontani et al., 2004](#)), and it has been found in sediments from freshwater lakes and hypersaline ponds ([Figure 4](#)). Recently, novel pentaunsaturated C_{38} and C_{39} alkenones have been found in the surface sediments of a perennially ice-covered Lake Fryxell in the Antarctica, which are thought to be synthesized by *Isochrysis* and/or *C. lamellosa* based on the genetics study performed on the same materials ([Jaraula et al., 2010](#)).

Biological Origin

To date, alkenones are known to be synthesized by a small group of haptophyte algae, which includes some coccolithophorids from the family Gephyrocapsaceae, such as the living species *E. huxleyi*, *G. oceanica*, and the extinct genus *Reticulofenestra* ([Marlowe et al., 1990](#); [Volkman et al., 1995](#)). Some of these taxa are coccolith producers and others are naked.

Figure 4 Examples of sites in which type A (blue) and type B (red) distributions of algae have been identified.

The low number of algal precursors is very important from the paleoclimatic or paleoceanographic standpoint, since the translation of the climatic event into a chemical signal depends on a limited number of organisms, thus providing a better constraint on the data interpretation. Conversely, in compounds synthesized by large groups of organisms, it cannot be excluded that changes in the sedimentary record could preferentially be related to variations in the precursor species rather than to climatic changes. In this respect, it has to be pointed out that alkenone analyses are based on extracts of sediments recovered at specific core sections, that is, there is no prior isolation of fossils from individual species of precursor organisms such as in Foraminifera-based geochemical proxies. Haptophyte algae are very small (on the order of $5\ \mu\text{m}$), and isolation of the carbonate tests from individual species is not feasible. In addition, there are alkenone-producing taxa that are naked, for example, *Isochrysis*. Thus, alkenone analyses of dry sediment always correspond to the composite contributions of all organisms producing these compounds present in the core section under study. Consequently, alkenone-derived SST estimates reflect a more integrated signal, with a high signal-to-noise ratio in the measurement, relative to those estimated via methods employing a small number of microfossils, such as the analysis of Mg/Ca from Foraminifera.

Despite the limited number of precursor species, these alkenones are widespread in the waters and sediments of all oceans ([Figure 4](#)), which shows that the precursor algae are widely distributed. This general distribution offers the potential to obtain paleoclimatic information from a wide diversity of marine environments that essentially cover the world's oceans, except the polar regions that are covered by sea ice ([Sikes et al., 1997](#)).

Calibration to SST

The variation in the degree of alkenone unsaturation (i.e., the number of the double bonds) obtained from the Quaternary sediments from around the world, in addition to the good correlation with planktonic foraminiferal oxygen isotope ratios during the past 550 000 years in a marine sediment core from the tropical Atlantic, led to the conclusion that the extent of unsaturation in alkenones is associated with SST ([Brassell et al.,](#)

1986). These authors thus proposed an index, known as the U'_{37} (eqn [1]), based on the relative abundance of di-, tri-, and tetraunsaturated alkenones as an approximation to quantify the degree of the unsaturation:

$$U'_{37} = (Me_{37:2} - Me_{37:4}) / (Me_{37:2} + Me_{37:3} + Me_{37:4}) \quad [1]$$

where $Me_{37:x}$ denotes the concentration of the C_{37} methyl alkenone with x carbon-carbon double bonds. To correlate the alkenone unsaturation index to temperature, laboratory cultures of *E. huxleyi* were grown under different temperatures, and the findings showed that the relationship between the two alkenone indices and growth temperature was linear in the range of 8–25 °C (Prahl and Wakeham, 1987; Prahl et al., 1988). However, the proportion of $Me_{37:4}$ alkenone is generally low in relation to $Me_{37:3}$ alkenone and $Me_{37:2}$ alkenone in marine sediments. Therefore, the original U'_{37} index is simplified to U'_{37} index (eqn [2] below) (Prahl and Wakeham, 1987):

$$U'_{37} = Me_{37:2} / (Me_{37:2} + Me_{37:3}) \quad [2]$$

Over the years, the U'_{37} index has become the more widely used index among the two, and most published calibrations (e.g., Conte et al., 2006; Müller et al., 1998) are based on this index. This is partly attributed to the fact that $C_{37:4}$ alkenones are rarely detected in the marine sediments. Consequently, in most cases, the U'_{37} values are equivalent to the U'_{37} values. The exception is probably in the polar regions, where some studies have found high relative abundance of $C_{37:4}$ alkenones in the sediments (e.g., Bendle et al., 2005). Some workers reported that in subpolar and polar settings where substantial amount of $C_{37:4}$ alkenones are found, U'_{37} yields more reasonable SST estimates that are comparable to other proxy data across the glacial-interglacial cycles (e.g., Bard, 2001; Calvo et al., 2002; Rosell-Melé, 1998). However, to date, there is still no consensus on the relationship of the relative abundance of $C_{37:4}$ alkenone with temperature. Some studies (e.g., Sikes and Sicre, 2002) indicate little or no relationship between $C_{37:4}$ alkenones and growth temperature, which suggests that in most cases, the U'_{37} ratio is probably a better proxy for paleotemperature estimate than U'_{37} . On the other hand, other studies (e.g., Harada et al., 2003; Rosell-Melé, 1998) found a negative correlation between the relative abundance of the $Me_{37:4}$ alkenone (the percentage of $Me_{37:4}$ alkenone, $\%C_{37:4}$, with respect to the sum of all C_{37} alkenones) and surface salinity in the high latitudes and suggested that $C_{37:4}\%$ could be used as a surface paleosalinity proxy. More recent work by Bendle et al. (2005) proposed that $\%C_{37:4}$ could serve as an indicator for polar water mass (low temperature and salinity) in the North Atlantic. Thus, further investigation is required to shed more light on the dependence of $C_{37:4}\%$ on temperature and/or salinity and its potential as a paleoclimatic proxy.

The laboratory culture study suggested a linear correlation between the alkenone unsaturation index and growth temperature, giving rise to the following equation: $U'_{37} = 0.034 \times T + 0.039$ ($r^2 = 0.994$, $n = 22$). Subsequently, many other calibration studies have also been performed, using other algal cultures, examining the relationship between water column particulates and *in situ* temperature measurements, or comparing core-top alkenone measurements with water column temperatures from oceanic databases. A decade

Figure 5 Comparison of the calibration equations of greatest general use for the estimation of SSTs from the unsaturation alkenone index (U'_{37}). The equation of Prahl et al. (1988) was obtained from cultures of *E. huxleyi* under controlled conditions. The core-top equation of Müller et al. (1998) and Conte et al. (2006), which were statistically identical, was obtained from measurements of core tops and comparison with sea surface temperatures from oceanic databases. The polynomial surface water calibration of Conte et al. (2006) was based on measurements of suspended particulate matter in the water column.

after the initial culture work (Prahl and Wakeham, 1987), surface sediments collected between 60°N and 60°S in the world oceans, spanning a temperature range from 1 to 29 °C and diverse biographical provinces, were analyzed for U'_{37} values (Müller et al., 1998). The resulting regression also demonstrated an exceptionally strong linear correlation with mean annual SST and a regression line ($U'_{37} = 0.033 \times T + 0.044$; $r^2 = 0.958$, $n = 370$) that is strikingly identical, within error limits, to that previously reported based on *E. huxleyi* cultures (Prahl et al., 1988; Figure 5). More recently, a more extensive global core-top compilation ($n = 592$) also found a statistically identical regression line (Conte et al., 2006). The strong agreement between the laboratory culture and core-top studies has led to most studies using one of these two equations for SST estimations. Furthermore, the results from some regional core-top calibration studies from the Atlantic Ocean (Rosell-Melé et al., 1995), the Indian Ocean (Sonzogni et al., 1997), and the Pacific Ocean (Prahl et al., 2006) further attest to the remarkable linear relationship between the alkenone unsaturation index and SST.

Even so, there is some debate on whether the relationship is linear over the whole range of the alkenone unsaturation index, or whether different equations should be used to account for deviations at the cold or warm ends ($U'_{37} \approx 0$ or 1, respectively). The linearity of the global core-top calibration over a large temperature range (~ 0 to 29 °C) seems to be confirmed by the core-top calibration studies (Conte et al., 2006; Müller et al., 1998), but contradicting conclusions could be drawn from previous regional studies that suggest a flattening of U'_{37} -SST relationship at high-temperature ends (e.g., Sonzogni et al., 1997) and those that argue against it (e.g., Pelejero and Calvo, 2003). Nevertheless, caution should be exercised in interpreting the U'_{37} -derived SST estimates at both temperature ends due to the low abundance of $C_{37:3}$ (warm end) and $C_{37:2}$ (cold end).

In addition, the fidelity of the alkenone paleothermometry could also be compromised by nonthermal physiological growth factors including nutrient and light availability, as evidenced by the findings of the laboratory culture studies (e.g., Epstein et al., 1998, 2001; Prahl et al., 2003; Versteegh et al., 2001), the suspended particulate matters in the water column (Popp et al., 2006), and the sediment (e.g., Prahl et al., 2006). The *E. huxleyi* culture study by Prahl et al. (2006) revealed that anomalously warm alkenone-derived SSTs are obtained under light-deprived conditions, while the opposite is true for nutrient-depleted conditions. Besides, the authors found that the alkenone/alkenoate composition also seems to respond to these physiological stresses, prompting the authors to propose that one could infer nonthermal physiological imprints on the alkenone-derived SST estimates by comparing the alkenone/alkenoate signature in sediments. However, it is not yet clear whether this index is representative of the global ocean.

In any case, it should be mentioned that the only alkenone distributions showing a direct and clear relationship with SST are those of type A, the most common distributions in the marine sediments. The distributions of type B alkenones in sedimentary samples give results that strongly deviate from the instrumental temperature values when their unsaturation indices are used for calculation with the above-mentioned equations, or other equivalent expressions available in the literature. The usefulness of type B alkenone distributions for temperature estimation remains to be demonstrated. In other words, the alkenones are good paleothermometers for marine systems, but up to now, they cannot be used for temperature estimation in brackish or freshwater environments.

Relationship Between Suspended Particulate Matters in Water Column and SST

Although the alkenone paleothermometer is one of the most robust proxies available to paleoceanographers, there are still some uncertainties that might constrain its accuracy in SST estimation. For instance, the global sediment core-top calibration differs substantially from the surface water calibration (see Figure 5). In the environment where SSTs are lower than

20 °C, the SST estimates based on core-top and culture calibration are consistently warmer than those derived from the surface water calibration, especially in the intermediate temperature range (10–15 °C). The underlying causes for this discrepancy are unclear. Based on the result of a simple model calculation, Conte et al. (2006) speculated that the combination of differential degradation of C_{37:3} over C_{37:2} alkenones, and the seasonality of alkenone production are the likely causative factors. Indeed, it is difficult to compare the C₃₇ alkenone composition in the water column and in underlying sediments due to the large differences in timescale the two signals represent. Water column particles are collected either by active filtration systems or by passive collection devices, namely, sediment traps. In the first case, sample collection may involve hours or 1 or 2 days at the most. In the second, samples may be collected for 1 or 2 years at weekly or monthly intervals in the most favorable cases. These samples are compared with sediment sections that may represent time-integrated periods of hundreds of years. Furthermore, sediments are not always collected with devices that could ensure collection of the true sediment–water interface section. It may happen that core-top sediments available for comparison are 1 or 2 ka old due to sediment mixing or to failure to recover the uppermost sediment during coring.

Comparison between alkenone analysis of filtered particles and *in situ* temperature measurements in the Gulf of Lions, under well-defined water column stratification conditions (Bentaleb et al., 1999), showed that the U^K₃₇ values of the suspended particles at 5-, 30-, and 1100-m depth corresponded to the water temperature where the maximum Haptophyceae abundance (30 m) occurred. Remarkably, the U^K₃₇ index at 5 and 1100 m was the same as that found at 30 m, indicating that the alkenones eventually incorporated into the sediment were likely to record the water temperature where the highest abundance of the source organism was found. These results are in general agreement with sediment trap data from 42° N in the eastern Pacific Ocean, where it was observed that alkenone production during periods of offshore stratification occurred at the subsurface chlorophyll maximum, and therefore, the U^K₃₇ index reflected the temperature measured at this depth

Table 1 Structures of the alkenones found in sedimentary environments

^aWater column depth (m).

(i.e., temperatures colder than the SST) (Prahl et al., 1993). A summary of studies dealing with correspondences between $U^{K'}_{37}$ indices in water column-suspended particles and underlying sediments is reported in Table 2. Good agreements were found in the Gulf of California (Göni et al., 2001), the Norwegian Basin (Thomsen et al., 1998), and the North Pacific off Japan (Sawada et al., 1998). In the Norwegian Sea, the $U^{K'}_{37}$ index of the sediment perfectly matched with the alkenone composition of material collected in a trap at 500-m water depth. The sediment traps deployed in the North Pacific off Japan extend over the deepest water column ever investigated (9200 m). No significant change was observed between the average $U^{K'}_{37}$ of sediment traps deployed at 1674, 4180, 5687, and 8688 m depth (13 samples collected in successive time intervals) and the underlying sediment (Sawada et al., 1998).

Cases of lack of correspondence in the alkenone composition in the water column and underlying sediments have also been reported (see Table 2 for some examples). In the Barents Sea, sediment trap data at 1840- and 1950-m water depth and underlying sediment (2050 m) showed considerable scatter. Resuspension and lateral advection were proposed as an explanation of these discrepancies (Thomsen et al., 1998). A major contrast between annual average sediment trap measurements at 3700 m and underlying sediment (4400 m) was reported in the northeast Atlantic (Rosell-Melé et al., 2000). Allochthonous alkenone input from elsewhere, for example, the polar front, instead of overlying waters, was proposed as an explanation. A transect of three sediment traps and underlying sediments in the northeast Pacific Ocean extending from the coast to the open ocean (Prahl et al., 1993) revealed an increase in $U^{K'}_{37}$ index between the sediment traps and sediments with increasing distance from the shore (Table 2): 0.04 (nearshore), 0.05 (further offshore), and 0.12 (gyre). The authors suggested that the observed differences did not necessarily involve selective degradation of the more unsaturated alkenones. The discrepancies could arise from other mechanisms, such as differential

preservation of the settling particles arriving at the seafloor over the year, because the $U^{K'}_{37}$ composition of the sediment trap particles collected monthly or weekly was not uniform.

Overall, these results show a good correspondence between $U^{K'}_{37}$ indices in water column particles and underlying sediments, indicating that the processes involving quantitative changes in C_{37} alkenones during particle settling do not result, in general, in significant changes of $U^{K'}_{37}$. To this end, the results of Sawada et al. (1998) concerning a water column of 9200 m are particularly significant.

Validity of Alkenone Paleothermometry in the Geological Past

Another important aspect in relation to the validity of alkenone paleothermometry throughout the Quaternary concerns the issue of whether the record could be affected by changes in evolving species. The dominance of *E. huxleyi*, the best-known alkenone-producing organism in the modern ocean, is restricted only to the last 70–80 ka, and the first appearance of this coccolithophorid in the oceans dates to 280 ka BP (Thierstein et al., 1977). The presence of alkenones in sediments before the appearance of *E. huxleyi* has been related to other algal species from the family *Gephyrocapsaceae* (*Gephyrocapsa* and *Emiliania* species) (Marlowe et al., 1990). However, studies comparing downcore SST profiles with abundances of coccoliths have not observed abrupt discontinuities paralleling the changes in predominant species. For example, the reversal in the dominant coccolithophorid species observed 74 ka BP at the Walvis Ridge did not significantly influence the alkenone unsaturation index–SST relationship (Müller et al., 1997). Similarly, in a study of a core situated in the central north Atlantic, significant changes in the relative composition of the C_{37} alkenones were not related to the reversals of the populations of *Gephyrocapsa* and *Emiliania* species over the last 290 ka (Villanueva et al., 2002). On a longer timescale, a comparison of the coccoliths and alkenone unsaturation index in the southeast Atlantic between 1500 and 500 ka BP

also demonstrates that evolutionary events and changes in species dominance (among *Pseudoemiliania lacunosa*, medium *Reticulofenestra*, *G. caribbeanica*, *G. oceanica*, small *Gephyrocapsa*, and others) did not affect the alkenone unsaturation index (McClymont et al., 2005). These results suggest that the alkenone paleothermometry can be applied to older sediments, prior to the first occurrence of *E. huxleyi* and *G. oceanica*. In recent years, alkenone paleothermometry has been successfully used to generate long-term SST records (e.g., Lawrence et al., 2006), showing the ability to provide reasonable temperature reconstruction for at least the last 5 My. In addition, the alkenone unsaturation index has recently been applied to older sediments of the Paleogene, where alkenone-based SSTs are similar to those inferred from other temperature proxies (Bijl et al., 2010), suggesting that even in sediments of this age, the index may still provide plausible SST estimates.

In fact, the influence of population genetics on the relationship between the alkenone unsaturation index and SST in older sediments could be examined using the relative abundance of the C_{37} and the C_{38} alkenones (C_{37}/C_{38}). This ratio shows a range of values in modern sediment and water column particulates between 0.7 and 1.4 (e.g., Conte et al., 1998, 2001) and around 1.8 in a culture study (Prahl et al., 1988). Therefore, if the alkenones found in sediments prior to the appearance of *E. huxleyi* exhibit C_{37}/C_{38} values within this range, one could assume that the fossil alkenone source organisms had a similar temperature adaptation mechanism in the lipids, validating the application of the calibration based on global surface sediments and culture studies. This approach has been attempted in several studies of samples from the late Pleistocene (e.g., Müller et al., 1997), across the mid-Pleistocene transition (e.g., McClymont et al., 2005) and the early Pliocene (e.g., Beltran et al., 2011). In addition, this ratio has been used to distinguish between marine and lacustrine alkenone producers during the Eocene (Weller and Stein, 2008), via the comparison of their sedimentary C_{37}/C_{38} data with a suite of published C_{37}/C_{38} values of several culture studies on different species of organism, that is, *G. oceanica* (Volkman et al., 1995), *Isochrysis galbana*, and *C. lamellosa* (Marlowe et al., 1984). Nevertheless, one should keep in mind that this ratio is empirical and must thus be interpreted with caution, since it has been found to vary as a function of growth temperature in the *E. huxleyi* cultures (Prahl et al., 1988), and some differences could be observed between cultured and natural alkenone producers (e.g., Conte et al., 1998; Yamamoto et al., 2000).

Alkenone Production: Depth and Seasonality

Due to the autotrophic lifestyle of the source organism of alkenones, that is, haptophyte algae, it is generally assumed that the alkenones reflect the algal growth temperature in the photic zone where light is available for them to carry out photosynthesis. Empirical evidence provided by the global core-top studies suggest that the best correlation exists for the water surface (0 m), suggesting that in most cases, the alkenones incorporated into the sediment are exported from the upper photic zone. Several water column studies suggest that the alkenone synthesizers could also thrive at the subsurface depths, such as the mixed layer (Bentaleb et al., 1999; Cortés et al., 2001) and thermocline waters (Ohkouchi et al., 1999).

Especially, in the latter case, where exported alkenones originated from the thermocline which could be as deep as 200 m and receive little heat from the sun, one might find that the alkenone-derived SST estimates are spuriously cold relative to the temperature of the overlaying surface water.

In spite of the best correlation found between the alkenone unsaturation index and mean annual SST (relatively to other seasons) exhibited by the global core-top compilation (Müller et al., 1998), care should be exercised in interpreting alkenone-derived SSTs as annual mean temperature estimates, especially in the high latitudes. This is because the seasonality of alkenone production in the ocean varies progressively with the latitudes. At high latitudes where temperatures are low and light is not available year-round, alkenone production is most likely limited to summer, thus, it is plausible that the alkenone-derived SSTs in this region might reflect summer SST instead of the annual mean. This has been observed in the core-top studies in the high latitudes in the Pacific Ocean (Prahl et al., 2010) and the Southern Ocean (Sikes et al., 1997). In contrast, the peak production of alkenones in the low and mid-latitudes occurs in winter or spring (e.g., Prahl et al., 1993), with some contribution during other seasons as well. Consequently, the sedimentary alkenones from these oceanic settings reflect a more integrated signal over the whole year.

Diagenetic Alteration of Alkenone Unsaturation Index

C_{37} – C_{39} alkenones are among the most refractory lipids known (Volkman et al., 1980). The causes of this resistance to degradation may be related to low solubility, protective package within the algal cells, and their unusual Z (*trans*) double bond configuration (Table 1), because many bacteria do not have enzymatic systems for the transformation of this type of double bond. The principal structural difference between the alkenones included in the U^K_{37} indices relates to the degrees of unsaturation, for example, $C_{37:2}$, $C_{37:3}$, and $C_{37:4}$. In general, the greater the degree of unsaturation, the more easily a lipid is degraded. According to the ratios previously defined (eqns [1] and [2]), SST estimation will be biased if selective degradation of $C_{37:2}$, $C_{37:3}$, or $C_{37:4}$ alkenones occurs during transport through the water column or in sediments. On the other hand, no bias in the SST estimates will be produced if all C_{37} alkenones are degraded in the same proportion, even in cases of extensive alteration.

Reported microbial degradation experiments of $C_{37:3}$ and $C_{37:2}$ alkenone mixtures with $U^K_{37} = 0.78$ and 0.6 under oxic, sulfate-reducing, and methanogenic conditions showed that the maximal percentages of consumption were 83, 43, and 80%, respectively, but that after this extent of degradation, the differences in U^K_{37} index were small, with a 0.4 °C bias in the worst case (Teece et al., 1998). Meanwhile, feeding experiments of zooplankton on alkenone producers indicated that the alkenone unsaturation index is not significantly altered by grazing, in which the C_{37} alkenones were found to be absent from the grazer bodies but abundant in the fecal pellets (Grice et al., 1998). The maximal U^K_{37} difference between dietary algae and released pellets was 0.03, equivalent to 0.9 °C. Nevertheless, recent studies focusing on the effect of the bacterial degradation on alkenones (e.g., Rontani et al., 2008) demonstrate that some aerobic bacteria have the

propensity to preferentially degrade the more unsaturated alkenones, introducing a 'warm' bias in alkenone-derived SST estimates.

After sedimentation, the transformation of organic matter, including lipids, strongly depends on the activity of microbiota and benthic organisms, at least during the first stages of diagenesis. Obviously, the degradation rates depend on sedimentary conditions. The concentrations of C_{37} alkenones decrease faster in oxic than in anoxic environments. Postdepositional oxidation episodes also involve strong decreases in C_{37} alkenone concentrations. However, the relevant point for paleoceanographic studies is whether the U'_{37} ratio is altered as a consequence of these diagenetic processes. In a study of core tops from the Peru margin, no significant changes in U'_{37} were observed, despite a decrease of total alkenone concentration of 30% (McCaffrey et al., 1990). In contrast, other studies (Gong and Hollander, 1999; Hoefs et al., 1998; Huguet et al., 2009) reported the selective degradation of the $C_{37:3}$ alkenone when comparing sediment records in oxic and anoxic sediments, resulting in spuriously warm SST estimates. Recently, epoxyketones were discovered in the sediments from the coastal region of southeast Alaska (Prah et al., 2010), which are produced as a consequence of selective alkenone degradation by an aerobic bacterial process (Rontani et al., 2008). By performing a semiquantitative calculation, it was proposed that the preferential degradation of alkenones could account for a considerable warming effect in the SST estimates. Since it is still in the early stage of development, more work is needed before the epoxyketones can be used to quantify the warm bias in SST estimates caused by the preferential degradation of alkenones in the sediments.

Stratigraphic Offsets Between the Alkenones and Other Sedimentary Proxies

In some depositional environments, vigorous currents or eddies are able to transport alkenones laterally over great distances from their source, as seen in the southwestern Atlantic (Benthien and Müller, 2000) and sediment drifts in the Cape Basin (Sachs and Anderson, 2003). Depending on the source of these advected alkenones, one could observe cold or warm biased SSTs in the sediment, or a discrepancy between different paleoceanographic proxies at the same site. However, lateral advection at sediment drifts does not necessarily result in erratic downcore SST variation patterns as demonstrated by Sachs and Anderson (2003) using a multiproxy approach and thorium-derived focusing factors.

Recent advancements in the radiocarbon technique provide additional ways of constraining the source origin of alkenones in marine sediments. For instance, at the Bermuda Rise (Ohkouchi et al., 2002) and the Benguela upwelling system off Namibia (Mollenhauer et al., 2003), studies using accelerator mass spectrometry (AMS) ^{14}C revealed discrepancies between the fine organic matter ($<63 \mu m$), including the algal C_{37} alkenones, and planktonic Foraminifera in the marine sediments, which implied that the alkenones were several hundreds or even thousands of years older than the Foraminifera that are taken as reference materials deposited at the same depth. This sedimentary asynchrony is explained by the strong differences in size between coccoliths (on the order of $5 \mu m$)

and the foraminiferal tests ($>150 \mu m$). In cases of resuspension due to intense bottom currents, the finer alkenone-bearing particles are susceptible to easier mobilization than the larger foraminiferal remains (Ohkouchi et al., 2002). The result is that older, previously deposited material can be remobilized and deposited in a new environment, leaving the fine fraction signal old with respect to the adjacent coarse material. However, the differences in particle size are not a priori very relevant for sedimentation through the water column because most algal remains arrive to the bottom as aggregates, for example, in the form of zooplankton fecal pellets ($\sim 50 \mu m$).

The ages of the marine sedimentary sections are currently determined from the composition of Foraminifera, either by interpretation of the $\delta^{18}O$ curve or by measurement of AMS ^{14}C in their carbonate skeleton. The potential temporal offset between alkenone SST and foraminiferal records may thus jeopardize the possibility of using alkenones for high-resolution studies in sedimentary environments because the signal that is stored in their composition may be older than the age determined for the sedimentary sections in which they are found.

Close comparison of high-resolution alkenone-derived SST and $\delta^{18}O$ profiles afford a practical way to detect whether this problem is significant in the sedimentary core sections under study. When both proxies exhibit synchronous changes, possible temporal offsets due to dissimilar sedimentation processes between organic matter and Foraminifera are negligible. This approach has been followed in some studies (e.g., Martrat et al., 2004), and in most cases, no sedimentation asynchrony was observed.

Concluding Remarks

Alkenone unsaturation indices are reliable tools for past SST estimations. The results from core-top analyses are coincident with laboratory culture experiments and confirm that the calibration equations obtained from cultures of *E. huxleyi* provide reliable estimates of mean annual SST in all oceans, except perhaps in the high latitudes where alkenone production is substantially biased toward the warm seasons. There is, however, a need for further investigation on the reliability of this equation in the cold- and warm-temperature ends. In this respect, sufficient quantitative information should be provided together with the alkenone studies, for possible SST reassessment in the future.

There is no consistent evidence of selective biogenic degradation of the $C_{37:2}$ and $C_{37:3}$ alkenones by organisms that consume them. Studies in the literature report little or no changes of U'_{37} as a consequence of C_{37} alkenone degradation in sediments or in the water column. These studies outweigh those in which significant changes were observed. More studies encompassing the whole range of U'_{37} values, different water column environments, and sedimentary conditions would help to clarify this issue.

In any case, the alkenone paleothermometry should be used with careful attention to the possible analytical biases due to low concentrations and irreversible adsorption in the chromatographic column. In addition, caution is warranted in the interpretation of the alkenone-inferred SSTs, when offsets are detected between the alkenone- and Foraminifera-derived

proxy records, as these offsets could reflect problems of asynchronous sedimentation.

In summary, the alkenone paleothermometry is a very useful tool for the understanding of the climatic evolution of the oceans, but its predictive power is strengthened by placing it in the context of the other paleoceanographic proxies.

Acknowledgments

The authors would like to thank J. O. Grimalt and J. F. Lopez for their great effort in putting together the first edition of this article. They are also grateful to J.-A. Flores for his generous contribution of a scanning electron microscope image of the coccolith of *Emiliania huxleyi*.

This article is a revision of the previous edition article by P. Loubere and W. Austin, volume 2, pp. 1618–1627, © 2007, Elsevier B.V.

Biology

Benthic Foraminifera are single-celled, eukaryotic, preferentially marine microorganisms with an external protective shell called a test. Benthic foraminiferal shells can be of either calcium carbonate secreted by the cell (calcareous) or of clay, silt, and sand size sediments cemented together (agglutinated). A few of the freshwater benthic Foraminifera have no shell (allogromids). Tests begin with an initial chamber (proloculus) secreted by the zooid, and grow through the progressive addition of further chambers, all of which are connected. Chambers are separated by a wall (septum) and joined by the foramen (aperture). The shells vary in size from being as large as over ~5 cm or even more (e.g., *nummulites*) to several microns. The shell shapes vary from being single chambered (unilocular) to chambers arranged in one, two, or more rows (uniserial, biserial, and multiserial, respectively) as well as with chambers arranged in spiral fashion (planispiral and trochospiral forms; [Figure 1](#)). The external surface of the shell is often ornamented with pits, ribs, spines, plates, etc. The benthic foraminifers communicate with the surrounding environment through an opening in the shell called the aperture. A web of protoplasm (pseudopodia) is extended through the aperture and other secondary openings called pores, to collect food material as well as for locomotion ([Figure 2](#)). The position of the aperture varies from species to species and this, combined with chamber shape, form of the test margin, structures on the test, and morphology, serves as the primary basis for species identification ([Boersma, 1980](#); [Loeblich and Tappan, 1987](#)).

At higher taxonomic levels, Foraminifera are subdivided on the basis of test-wall-forming architecture ([Loeblich and Tappan, 1987](#)). This has largely to do with the organization of calcite crystals in relation to the organic membrane that serves as a template for test secretion. A review of classification is presented in [Sen Gupta \(1999\)](#). There are three significant groups: (1) test made of organic material (Allogromida), (2) test particles attached to a proteinaceous or mineralized matrix (agglutinated, 3 orders), and (3) test wall made of secreted carbonate (calcareous, 8 orders). At the generic and species levels, Foraminifera are recognized by test morphology.

Benthic Foraminifera reproduce by both sexual and asexual modes with alternation of generations reported in several species (see [Goldstein, 1999](#)). They are abundant in nearshore coastal waters and their abundance usually decreases with increasing water depth. Benthic Foraminifera evolved during the Cambrian and at present, they are very diverse, with over 10000 species reported from different parts of the world's oceans.

Ecology

Benthic Foraminifera live in the upper 5–10 cm of the sediments in all marine environments. Their distribution is

controlled by the physical (temperature, salinity, depth, turbulence, grain size, etc.), chemical (pH, dissolved oxygen, nutrients, etc.), and biological (organic matter, predators, etc.) characteristics of the sediments and the overlying seawater. Out of all these parameters, shallow water coastal benthic Foraminifera are able to tolerate a large range of seawater temperature and salinity ([Saraswat et al., 2011](#)). However, organic flux and dissolved oxygen are limiting factors for both the surface and subsurface distribution of the majority of benthic Foraminifera. Benthic foraminiferal distribution (including abundance, diversity, species richness, etc.) varies with sediment depth ([Goody, 2003](#); [Loubere and Fariduddin, 1999a](#); [Mackensen and Douglas, 1989](#); [Sun et al., 2006](#)). The depth distribution of benthic Foraminifera in an oligotrophic setting is controlled by food availability, while in eutrophic waters, the depth to which benthic Foraminifera can survive depends on oxygen levels, as explained by the TROX model (trophic-oxygen model) ([Figure 3](#); see [Jorissen et al., 2007](#), for review). The depth-wise species zonation is better developed in the deep oceans than in shallow waters because of differing turbulence conditions. However, in restricted environments such as silled basins and within the sediments, depletion of oxygen does not seem to be a limiting factor for a suite of benthic species. Living Foraminifera are routinely found in subsurface or basinal settings where oxygen levels are very low, and some have special adaptations to these conditions ([Bernhard, 1996](#)). Many are active searchers within their environment and may have associations with larger organisms. These associations may involve adaptation to the use of larger organism burrows as a way of having access to aerated water deeper within the sediments and so overcoming the low oxygen barrier ([Loubere et al., 1995](#)).

The calcareous (both calcite and aragonite) forms are present in all types of marine environments above the carbonate compensation depth (CCD). The agglutinated benthic Foraminifera are more abundant in brackish waters, and they also survive below the CCD. In low salinity and brackish environments, calcareous foraminiferal diversity is severely reduced to only one or two tolerant species, mainly because of low pH. In restricted or biologically challenging environments, agglutinated forms become dominant. Some Foraminifera in reef settings maintain symbionts in a manner similar to coral coelenterates ([Hallock, 1999](#)). Foraminifera may live attached to rock or plant surfaces as epiphytes; they may be epibenthic on sediment surfaces or shallow to deep infaunal in soft substrate ([Jorissen, 1999](#)). Foraminiferal test morphology appears related to habitat preference ([Corliss, 1985](#)).

On the larger scale, Foraminifera show two patterns in distribution and abundance of taxa. Firstly, they are zoned according to water depth. Zonation, and the taxa involved, varies from one region to the next, but the underlying factors are probably the same. In the shallow marine setting, on the

Figure 3 TROX model explaining factors affecting benthic foraminiferal distribution, especially in deep-sea environments. Modified from Jorissen FJ, Fontanier C, and Thomas E (2007) Paleooceanographical proxies based on deep-sea benthic foraminiferal assemblage characteristics. In: Hillaire-Marcel C and de Vernal A (eds.) *Proxies in Late Cenozoic Paleooceanography: Pt. 2: Biological Tracers and Biomarkers*, p. 263–326. Amsterdam: Elsevier.

inner continental shelf, substrate and physical conditions are highly variable, resulting in complex and patchy distributions. As with other organisms, a fundamental boundary exists between the sunlit ocean where plants are abundant and outer shelf and deeper habitats which are in the dark. Zonation of foraminiferal taxa is likely driven by the main ocean temperature gradient and the exponentially decreasing supply of useable organic matter with water depth. Beyond the continental shelf, the substrate becomes generally more uniform, allowing for broader distribution of biofacies (Culver, 1988). The second pattern of benthic foraminiferal distribution is biogeographic and strongly associated with latitude (Culver and Buzas, 1999). This pattern is most prominent with neritic, shallow ocean taxa and is clearly related to ocean thermal gradients.

From Living to Fossil

Foraminifera do not die a natural death, as either the whole cell divides into several small nuclei with little protoplasm, each of which grows into an individual, or the protoplasm of two individuals combines together, divides into spores, two of which fuse together to give rise to an individual. Thus, the original cell material keeps on multiplying and giving rise to offspring. Therefore, foraminiferal populations generate tests which accumulate in the sediments as a result of predation or reproduction. In reproduction, foraminiferal cytoplasm subdivides into zooids which abandon the parent's test. Test production is thus a function not only of standing stock of a taxon but also of generation time. Thus, the foraminiferal 'death' assemblage need not bear close numerical similarity to the living community.

Beyond the initial 'death' assemblage formation, there are a number of processes that influence what is preserved in the longer term (Murray, 2006). Test production occurs in a range of microhabitats from the epiphytic to deep infaunal, and this production is then mixed into accumulating sediments and through the geochemically active diagenetic zone within the upper 10–50 cm of the seabed. In this zone, sediments are bioturbated, well mixed, and passed from generally oxic conditions at the surface to anoxic, even sulfate reducing, conditions at depth. Geochemical gradients are generated in response to oxidation of organic matter within the sediments. Acids produced from this, and probably also associated biological activity, may degrade carbonate shells. The dissolution may lead to partial decalcification of calcareous foraminiferal tests and even to an increase in abundance of agglutinated tests in the death assemblages (Murray and Alve, 1999). The taphonomic alteration of calcareous benthic species depends on surface texture. Contrary to that, the agglutinated tests are relatively less prone to diagenetic changes and degrade in a more arbitrary manner, indicating that their degradation not only depends on test architecture but also the physical/mechanical processes (Berkeley et al., 2009). There is a net, and species selective, loss of tests within the sediment column. The extent of this depends on the intensity of the geochemical gradients (supply of easily oxidized organic carbon), the species involved, and the microhabitat in which the species lived. Deeper infaunal taxa have generally better preservation potential than any more lightly calcified epibenthic species. Thus, the living foraminiferal community represents a moment in time

and transient conditions, while the fossil assemblage represents the integration of production under a number of different conditions over long time period.

Benthic Foraminifera as Recorders of the Quaternary

The variation in abundance, morphology, and composition of the foraminiferal tests is an adaptive response of Foraminifera to changes in the environments they inhabit. Thus, the climatic response of benthic Foraminifera is used to infer past environmental conditions. Various characteristics of the benthic foraminiferal tests that are used to infer past climatic variations include total foraminiferal number, species abundance, assemblages, test size/diameter, coiling direction, average number of chambers, proloculus size, test abnormalities, stable isotopic composition of the tests, trace metal composition of the test, etc. (Boltovskoy and Wright, 1976; Murray, 2006; Sen Gupta, 1999).

Use of presence-absence and indicator taxa is the simplest approach and has been developed extensively for industrial (petroleum exploration) applications. However, taxa respond to a spectrum of environmental factors, so that it is often difficult to confidently determine the nature of environmental changes responsible for observed events in the fossil record. Laboratory culture studies can help elucidate specific responses to particular parameters, which can then be applied to fossils (see Linshy et al., 2007 for review; Nigam et al., 2008; Saraswat et al., 2011). Assemblage analysis is more time consuming but can be more revealing of unique biofacies. With careful organization of a modern data set, it is possible to make quantitative calibrations of seabed fossil assemblages to important environmental variables (see Loubere and Qian, 1997, for theory). Uniformitarian assumptions then allow for the development of 'transfer functions' with which paleoenvironmental parameters may be at least semiquantitatively estimated from fossil assemblage composition. Abnormalities in the tests in response to anthropogenic pollution have been reported, both from the field as well as in controlled laboratory culture studies (see Nigam et al., 2006 for review; Nigam et al., 2009a; Frontalini and Coccioni, 2011). The stable isotope record of benthic Foraminifera is one of the primary correlations and age dating tools in the Quaternary, particularly oxygen isotopes (Lisiecki and Raymo, 2005). The primary driver of oxygen isotope shifts in calcareous tests is changing ice volume at the poles, with a secondary imprint from changes in local temperature, precipitation, evaporation, and runoff. Carbon isotope signals are more complex, incorporating shifts in surrounding water mass, global transfers of carbon isotopes between ocean and continents, and microhabitat selection for infaunal taxa (Schumacher et al., 2010). Trace elements in benthic Foraminifera serve as recorders of global ocean circulation and chemical state of the ocean (Bryan and Marchitto, 2008; Lear et al., 2008; Toyofuku et al., 2011). They also have the potential for recording local environmental geochemical conditions.

Applications

Intermediate Water Oxygenation

Benthic Foraminifera live both on the surface of sediments (epifaunal) as well as several centimeters below (infaunal).

The infaunal forms, in general, can tolerate low dissolved oxygen conditions. This species-specific response of benthic Foraminifera to variation in dissolved oxygen concentration in the ambient seawater (Bernhard and Sen Gupta, 1999; Gooday et al., 2010) has been used to reconstruct past variation in shelf water oxygenation (den Dulk et al., 2000; Nigam et al., 2009b). The high relative abundance of miliolids has been suggested as an indicator of periods of increased ventilation in the northern Arabian Sea, whereas deep-infaunal species indicate oxygen-deficient waters. The Quaternary changes in the intensity and extent of the oxygen minimum zone in the northern Arabian Sea, inferred from benthic foraminiferal assemblages, have been correlated with a change in organic matter flux in response to monsoon-controlled productivity changes (den Dulk et al., 2000). The development of a seasonal shallow water hypoxic zone off the west coast of India has been traced to preanthropogenic time, based on increased abundance of rectilinear benthic Foraminifera in low oxygen waters (Nigam et al., 2009b).

Surface Productivity

Benthic foraminiferal assemblages preserved in sediments are strongly affected by the supply of labile organic matter to the environment (reviewed in Gooday, 2003). This is particularly true for the deep ocean, where other environmental factors are more uniform. Above the depth at which thermodynamic dissolution (due to bottom water calcite undersaturation) begins to strongly affect foraminiferal preservation, it can be argued that organic carbon flux, and its seasonal variation, is the primary determinant on assemblages (Corliss et al., 2009; Soma and Gupta, 2010). Organic carbon flux to the seabed in the open ocean is a function of new biological production in the upper ocean. This new production depends on upper ocean nutrient distribution and on patterns of wind-induced upwelling. Thus, reconstructing biogenic flux to the seafloor and upper ocean productivity provides windows to past oceanic nutrient distributions, circulation, and wind fields. These are important variables in the control of atmospheric CO₂ content and in the modeling of global climate change mechanisms.

Analysis of a large suite of surface sediment fossil assemblages in a data set organized to minimize organic carbon flux correlation with other potentially significant ecological variables has made it possible to construct a transfer function for upper ocean productivity (Loubere and Fariduddin, 1999b). In higher productivity settings, infaunal taxa are abundant, whereas in the oligotrophic domain, the assemblages are dominated by epifaunal and opportunistic forms. Down-core assemblages can thus be used to estimate past oceanic productivity.

The benthic foraminiferal productivity transfer function has been used extensively in the eastern equatorial Pacific since this region is globally important to the marine new production budget and also to the exchange of CO₂ between ocean and atmosphere. Application of the transfer function in a regional network of cores, and its comparison to other paleoceanic tracers, has allowed reconstruction of upper ocean nutrient concentration gradients and patterns of biological production as they were during the late Pleistocene glacial intervals (Loubere et al., 2003). This work has demonstrated important changes in nutrients and productivity over glacial–interglacial

cycles that would have affected oceanic transfer of CO₂ to the atmosphere, and hence, the atmospheric CO₂ cycles recorded in ice cores.

High primary productivity off South-West Africa during Heinrich 2 (25.4–24.3 ka BP) and 1 (16.8–15.8 ka BP) was inferred from increased abundance of infaunal and deep-infaunal benthic foraminiferal specimens, along with high benthic Foraminifera accumulation rates. At present, this region is marked by highly seasonal primary productivity (Zarriess and Mackensen, 2010). A distinct increase in the abundance of opportunistic species feeding on phytodetritus (*Epistominella exigua*) or adapted to elevated but intermittent organic carbon fluxes (*Bulimina aculeata* and *B. marginata*) has been inferred to indicate episodes of recurrent phytoplankton bloom at the end of marine isotopic stage (MIS) 13 and during the early and late parts of MIS 11 in the Blake Outer Ridge, whereas increased abundance of infaunal taxa (*Uvigerina* spp. and *B. alazanensis*) during glacial MIS 12 and 10 indicates sustained organic carbon delivery and diminished pore water oxygenation (Poli et al., 2010).

Monsoon

High turbulence near the mouths of rivers, in response to freshwater influx from the rivers, favors rounded symmetrical benthic Foraminifera (Nigam et al., 1992). Additionally, the morphology of selected benthic Foraminifera in the shallow water regions close to river mouth varies with changes in freshwater influx from the rivers (Nigam and Khare, 1995). These characteristics have been used to infer cyclic changes in the monsoon during the late Quaternary (Nigam et al., 1995). Large salinity variations in shallow water regions also favor characteristic benthic foraminiferal assemblages. *Ammonia beccarii*, along with a number of other calcareous taxa (*Haynesina* sp., *Elphidium* spp., *Quinqueloculina* spp., and *Rotalinoides annectens*) and agglutinated taxa (*Haplophragmoides* sp. and *Ammobaculites formosensis*), dominate a large proportion of the Pearl River estuary, southeast China Sea, and a gradual increase in their relative abundance has been used to infer declining fluvial influx since the mid-Holocene (Garrett, 2010). The establishment of the modern alternating northeast and southwest monsoon system in the Indian subcontinent at 2.8 Ma and its prevalence throughout the Quaternary was inferred on the basis of increased abundance of benthic foraminiferal taxa indicating strongly seasonal pulsed organic matter flux (Gupta and Thomas, 2003).

High Latitude Glaciations

In the middle to high latitudes, the pattern of repeating glacial–interglacial cycles through the Quaternary has left a clear signal in the marine sedimentary archive. The sensitivity of restricted exchange environments, such as fjords, to climatic and environmental change is increasingly recognized. These glacially overdeepened and often sheltered coastal environments preserve exceptionally well-resolved sedimentary records close to the land–ocean interface. The associated benthic foraminiferal assemblage changes preserved in these sediments provide an excellent record of paleoenvironments, from the deep ocean to the shallow subtidal zone. In the high latitude coastal and shelf

sea environments, where salinities are often reduced and planktonic Foraminifera are absent, benthic Foraminifera represent an extremely valuable microfossil group. In recent years, a number of very detailed paleoclimatic records, based on benthic Foraminifera, have emerged from these environments, many highlighting the nature and instability of Holocene paleoclimates (e.g., Husum and Hald, 2004).

Feyling-Hanssen (1964) pioneered the use of benthic Foraminifera in the reconstruction of late Quaternary paleoenvironments in deposits from the Oslofjord area of southern Norway, employing what was termed an *ecostratigraphic* approach. The presence of distinct benthic foraminiferal biofacies, including that of the ice edge, has also been inferred (Ishman and Szymeczek, 2003). Recently, Majewski (2010) summarized benthic foraminiferal distributions from the west Antarctic fjord environments and their paleoecological implications. Increased relative abundance of the benthic foraminiferal species *Cassidulinina neoteretis* from the Bølling/Allerød through the Younger Dryas suggests that Atlantic Intermediate Water entered the Kangerlussuaq Trough during the Allerød and the Younger Dryas via the Irminger Current and further that advection of Atlantic Intermediate Water into the Kangerlussuaq Trough, south of the Denmark Strait, promoted melting and retreat of

the marine portions of the Greenland ice sheet (Jennings et al., 2006). A high-resolution record of glacial retreat and Holocene climate change in the Weddell Sea side of the Antarctic Peninsula has been generated on the basis of benthic foraminiferal assemblages. It is inferred that the most glacier-proximal conditions lasted until ~8800 years BP, as indicated by *Criboelphidium* cf. *webbi*. A marked increase in *Paratrochammina bartrami* and *Paratrochammina antarctica*, the major constituents of the *P. bartrami*–*P. antarctica* assemblage after ~3500 years BP, indicates the onset of the neoglaciation interval (Majewski and Anderson, 2009).

Sea Level

The environmental gradients of intertidal settings are often extreme and include large changes in salinity, subaerial exposure, and marked changes in pH. For this reason, intertidal environments often exhibit a marked intertidal zonation pattern and benthic Foraminifera. In particular, the cosmopolitan agglutinated species *Trochammina inflata*, *Miliammina fusca*, and *Jadammina macrescens* appear to be universal in their occurrence and vertical zonation (Figure 4).

Figure 4 Zonation of benthic foraminiferal taxa down the continental slope of the Gulf of Mexico. These regions can be distinguished by the assemblage of Foraminifera found in the sediments. Notice how the distributional pattern is clearly influenced by water depth and regional substrate (e.g., Mississippi delta and Florida/Yucatan carbonate platforms). Zonation named taxa: 1 = *Ammonia*, 2 = *Elphidium*, 3 = *Miliolid*, 4 = *Saccammina*–*Ammobaculites*, 5 = *Rosalina*–*Hanzawaia*–*Islandiella*, 6 = *Asterigerina*–*Soritid*–*Archaias*, 7 = *Planulina*, 8 = *Elphidium*–*Hanzawaia*–*Bigenerina*, 9 = *Brizalina*, 10 = *Bulimina*, 11 = *Islandiella*, 12 = *Eponides*–*Nuttallides*. Redrawn from Poag W (1981) *Ecologic Atlas of Benthic Foraminifera of the Gulf of Mexico*, 174 p. Woods Hole, MA: Marine Science International, with permission.

Scott and Medioli (1978) provided an elegant illustration of the application of benthic foraminiferal intertidal zonation to the reconstruction of past sea level in a study of salt-marsh deposits in Nova Scotia, Canada. They argued that past sea-level positions could be reconstructed from sediment cores with a precision of ± 0.05 m. In particular, the use of *Trochammina macrescens*, which is the highest occurring salt-marsh Foraminifera living on the salt-marsh surfaces of New England and the Canadian Maritimes, is arguably the most accurate sea-level indicator in the world (Figure 5; Gehrels, 2002). In sediment records, particularly those overlying hard, difficult to compact substrates, the presence of species such as *T. macrescens*, which occurs in a narrow zone near the highest astronomical tide level, provides a very useful indicator of former sea level. When dated, these salt-marsh deposits provide so-called sea-level index points, and these may be combined to provide a record of changing regional sea levels (see Gehrels, 2002).

In formerly glaciated regions, where isostatic uplift of the Earth's crust is active, salt-marsh deposits are rare, and isolation basins often provide the best available evidence of former sea levels. In such settings, basins with well-defined rock sills can become isolated from the sea during uplift, so that they preserve a sedimentary record of the marine to freshwater transition. This transition, once dated, provides a sea-level index point. Numerous basins within a region, with rock sills at differing altitudes, provide a series of sea-level index points. A detailed study by Lloyd (2000) of Loch nan Corr, an isolation basin in north west Scotland (a region heavily glaciated during the Last Glacial Maximum (LGM)), reveals a total of eight foraminiferal biozones, with the lower zones rich in calcareous estuarine and shelf species, dominated by *Haynesina germanica*. As the Loch nan Corr basin went through the isolation process, the foraminiferal assemblages recorded a steady decrease in the number of calcareous taxa and a gradual increase in agglutinated taxa. Initially, *J. macrescens* dominated, giving way to *M. fusca*, until freshwater conditions are finally indicated by the sudden appearance of testate amoebae. Sea level also plays an important control in many shelf sea processes, exerting a particularly strong influence on the position of shelf sea fronts that separate the seasonally stratified from well-mixed water columns of the middle and high latitudes. Typically, as sea levels rise following deglaciation, continental margins are flooded and the locations of fronts migrate landward across the shelf. Austin and Scourse (1997) used benthic foraminiferal assemblage and stable isotope data from a core in the central Celtic Sea to test the temporal evolution from a mixed to stratified water column during the Holocene transgression of the European shelf.

Benthic foraminiferal assemblages show marked faunal changes as 'high-energy' epifaunal species, such as *Cibicides lobatulus*, give way to 'low-energy' infaunal species, such as *B. marginata*, during sea-level rise. Since the mixed water column situation will translate summer heating throughout the depth of the water column, summer bottom water temperatures, when Foraminifera are growing and calcifying their tests, will be relatively high. However, once sea level has risen sufficiently to enable the water column to stratify, summer heating of the surface ocean is no longer mixed throughout the depth of the water column, and summer bottom water temperatures remain low. As well as the benthic assemblage changes, Austin and Scourse (1997) used stable isotopes recorded in two benthic species, *Ammonia batavus*

and *Quinqueloculina seminulum*, to infer a mid-Holocene cooling of 4–5 °C in bottom water temperatures as stratification of the central Celtic Sea was established, following sea-level rise.

Thermohaline Circulation

The continuous inter-basin exchange of seawater due to the difference in its temperature and salinity in different oceans is termed as thermohaline circulation. It includes formation of deepwater in the northern Atlantic and around Antarctica, distribution of this deepwater to all major oceans as deepwater, bottom water or intermediate water, and a subsequent movement of warm water from the Pacific and the Indian Ocean, back to northern Atlantic as surface currents.

Changes in deepwater production in the northern Atlantic and a subsequent change in ventilation of deep, intermediate, and bottom waters are a part of thermohaline circulation changes during glacial–interglacial time periods as well as long-term adjustments in thermohaline circulation. Such periodic adjustments of thermohaline circulation alter physicochemical characteristics of intermediate, deep, and bottom water, which in turn affect benthic Foraminifera. Therefore, benthic Foraminifera are ideal to track changes in thermohaline circulation. Extinction and decreased abundance of selected benthic foraminiferal species are often used to track changes in thermohaline circulation. In addition, stable oxygen and carbon isotopic ratios of selected benthic Foraminifera have also been used to infer past changes in thermohaline circulation. A decrease in abundance and disappearance of elongate, bathyal–upper abyssal benthic Foraminifera (Extinction Group = Stilosomellidae, Pleurostomellidae, some Nodosariidae) in the northern Indian and southwest Pacific Ocean at the time of onset of the mid-Pleistocene transition was attributed to the increased production of cold, well-ventilated Glacial North Atlantic Intermediate Water (Hayward, 2002; Kawagata et al., 2006). The dominance of epifaunal species within the pre-S5 and post-S5 sediments, combined with the low abundance and dominance of infaunal taxa at the base and top of S5, has been ascribed to changes in state of anoxia resulting from variation in ventilation of the deep waters (Nolet and Corliss, 1990). Differences in the abundance of oxygen-sensitive and dissolution-prone benthic foraminiferal species between the LGM and the Holocene in the abyssal waters of the southwestern Gulf of Mexico were used to infer changes in the production of glacial North Atlantic deep water (NADW) during LGM and NADW during the Holocene (Machain-Castillo et al., 2010).

Storm/Tsunami

Long-term past records of storms/tsunami events can help us understand recurrence intervals of these events. The storms/tsunamis leave behind evidence in several forms, especially the material transported from its natural place of occurrence to an unlikely location. Storms/tsunamis can erode sediments from deeper waters, transport them to shallow regions against the normal gradient, and redeposit them in shallower regions. Even though it is possible to determine anomalous origin of the sediments, based on the sediment texture and composition, it is difficult to ascertain their origin from the landward or seaward side of their occurrence. Benthic Foraminifera which have characteristic depth zonations of different species can

Figure 5 The foraminiferal zonation at Sanborn Cove marsh, Machiasport, Maine, in relation to the zonation of plants and the frequency and duration of tidal flooding. The foraminiferal zones (1A, 1B, 2A, 2B) correspond to the zones from Nova Scotian marshes described by Scott and Medioli (1978), except for the fact that *Jadammina macrescens* and *Balticammina pseudomacrescens* are grouped as *Trochammina macrescens* in Nova Scotia. MHW – mean high water (1.97 m above sea level). Reproduced from Gehrels WR (2002) Intertidal foraminifera as palaeoenvironmental indicators. In: Haslett SK (ed.) *Quaternary Environmental Micropalaeontology*, pp. 91–114. London: Arnold.

help determine the direction of transport of sediments. Benthic Foraminifera, being very small and light in weight, also get transported along with the sediments during such events. Benthic Foraminifera show a marked zonation in shallow waters, with coastal assemblages being significantly different than deep-water assemblages. Thus, the transport of sediments against gravity by extreme events like storms or tsunamis can be inferred on the basis of benthic Foraminifera (Mamo et al., 2009).

Making use of modern storm traces (offshore benthic Foraminifera in marsh sediments), intense storm activities (six storms) were inferred between 0 and 1000 years BP interval along the South Carolina coast. Three additional storm events were identified during the 1000–2000 yr BP interval and two between the 2000 and 3000 yr BP interval (Scott et al., 2003). The presence of ca. 12 000–10 000-year-BP-old sediments above ca. 8000-year-BP-old sediments in cores collected from the eastern Arabian Sea was attributed to ancient storm–tsunami events, based on characteristic benthic foraminiferal assemblages (Nigam and Chaturvedi, 2006). Here, inverted sediments were found sandwiched between typical marine sedimentary sequences. The top of the inverted section was older than the top of the typical sequence just below it. This inverted sequence contained benthic Foraminifera that are found in comparatively deeper waters than their present water depth, which ruled out the possibility of transport of this inverted sequence from the landward side of its present location. The older age and deeper benthic foraminiferal assemblage in the inverted sequence were inferred to have been caused by transport of these sediments from a deeper location by a storm or tsunami. A second similar storm–tsunami-deposited a foram assemblage that was identified from ca. 10 000-year-old sediments over a normally deposited, ca. 7000-year-old sequence in the same region. Schafer and Medioli (2009) inferred erosion and transport of sediments from the adjacent inner shelf by an onshore-directed storm/hurricane event based on the presence of benthic and planktic foraminiferal tests in a core collected from the landward side of a baymouth barrier in Chezzetcook, Nova Scotia, Canada.

Marine Archaeology

Calcareous benthic Foraminifera are exclusively marine. Therefore, the presence of autochthonous fossil calcareous benthic foraminiferal shells can be considered proof of marine environments. This has been used to settle a long-standing controversy regarding the usage of a large rectangular tank of Harappan (Indus Valley Civilization) times, excavated at a location far away from the present coast. Large triangular stones with a hole were recovered from the tank. It was long debated whether the stones were used as anchors, suggesting the structure was part of a dockyard for small ships, or whether the stones were used as deadweight to draw water out of the freshwater tank. The presence of fossil benthic foraminiferal shells, characteristic of shallow water, in the large rectangular structure confirmed it to be the dockyard for small ships (Nigam, 1988). A distinct difference in benthic foraminiferal assemblage characteristic of salt marsh and lagoon was used to reconstruct the evolution and subsequent fifth-century human settlement of San Francesco del Deserto Island in the Lagoon of Venice (Barbero et al., 1997).

Pollution Monitoring

Benthic Foraminifera live in all marine environments, from the intertidal regions to the deepest trenches. In shallow water coastal habitats, industrial waste effluents and domestic sewage outfall affect benthic Foraminifera. The pollutants affect the normal life cycle of benthic Foraminifera, resulting in highly deformed and stunted shells. The shells from polluted regions often also lack ornamentation (Bhalla and Nigam, 1986; Geslin et al., 2002; Scott et al., 2001; see Nigam et al., 2006 for review). Anthropogenic pollutants not only affect the morphology of benthic Foraminifera but also their diversity and abundance (Arieli et al., 2011; Frontalini and Coccioni, 2008, 2011). This distinct benthic foraminiferal response to anthropogenic pollution has often been used to reconstruct historical changes in pollution levels (Scott et al., 2005; see Nigam et al., 2006 for review). A gradual increase in pollutants over a period of time will affect the benthic foraminiferal population in the vicinity with increasing severity. Thus, temporal changes in the number of deformed or stunted specimens can be used to infer changes in the concentrations of pollutants. The change in benthic foraminiferal abundance has also been used to delineate shifts in the level of mining activity in monsoon-dominated tropical regions, as huge precipitation and surface runoff during monsoon season carries mining waste to the estuaries, leading to increased total suspended matter and thus turbidity, which affects benthic Foraminifera (Panchang et al., 2005).

Introduction

Molecular fossils, 'biomarkers,' add to the growing arsenal of climate indicators scientists are using to reconstruct climate history and understand what causes climate to change. Advances in analytical chemistry and instrumentation over the last two decades have expanded the analytical window in which organic geochemists can routinely work. Precise and highly sensitive mass spectrometers that can determine molecular structures and isotope ratios are now coupled to gas and liquid chromatographs that can separate the complex mixtures of organic constituents found in geologic samples into pure components.

As more geoscientists become familiar with these new techniques, there are likely to be tremendous advances in organic geochemical climate proxies. This article reviews some of the more promising and novel biomarker proxies now being used in paleoclimate research. The article is organized around the climate parameters of most interest to paleoceanographers and paleoclimatologists: temperature, salinity, and sea ice.

Biomarker Proxies of Temperature

The reconstruction of ocean and lake surface temperatures is central to understanding past climatic changes. Impressive advances have been made in organic geochemical approaches to temperature reconstructions. This article focuses on the two most promising and widely applied organic geochemical water temperature proxies: U^k_{37} and TEX_{86} . A relatively new organic geochemical indicator of air temperature known as cyclization ratio of branched tetraethers/methylation index of branched tetraethers (CBT/MBT) is also briefly discussed.

Alkenone Paleothermometry

The discovery of temperature-controlled unsaturation patterns in long-chain ketones and alkenones (nC_{37} – nC_{39} methyl and ethyl ketones) in the mid-1980s (Brassell et al., 1986), and their identification as biomolecules unique to prymnesiophyte algae, principally the coccolithophorid *Emiliania huxleyi* (Marlowe et al., 1984; Volkman et al., 1980), was a watershed event in paleoclimate research. For the first time paleoceanographers had a tool for reconstructing sea surface temperatures (SST) that was unambiguously derived from organisms living in the uppermost part of the ocean where sunlight can penetrate, that was not influenced by the chemical composition of seawater (as, for instance, oxygen isotope ratios in planktonic Foraminifera are), and that was not corrupted by the chemical composition of ocean bottom water. Thus, a sizeable advantage of the

alkenone paleotemperature technique over other temperature proxies, such as Mg/Ca ratios in planktonic Foraminifera or faunal (Foraminifera, radiolarians, diatoms) assemblage changes, is the fact that alkenones are preserved in the sediments even after the dissolution of the calcareous remains of their producers. The technique can, therefore, be applied in regions where other techniques would fail (e.g., the Southern Ocean).

The original definition of the unsaturation ratio (U^k_{37} index) included the tetraunsaturated C_{37} alkenone (Brassell et al., 1986), which was later omitted due to its insignificant contribution ($U^k_{37} = C_{37:2}/(C_{37:2} + C_{37:3})$). Prahl et al. (1988) were the first to publish a quantitative calibration of the U^k_{37} index to growth temperature ($U^k_{37} = 0.034 T + 0.039$, $r^2 = 0.994$) based on cultured *E. huxleyi*, and initial field measurements showed that this calibration reproduced SSTs in the northeast Pacific Ocean (Prahl and Wakeham, 1987). This calibration has since been widely used for the reconstruction of past SSTs in most parts of the world's oceans (e.g., Bard et al., 1997; Herbert et al., 2001; Koutavas and Sachs, 2008; Pahnke and Sachs, 2006; Sachs and Lehman, 1999). Extensive alkenone analyses on a global set of core-top samples and correlation of the U^k_{37} index with overlying mean annual SSTs ($U^k_{37} = 0.033 T + 0.069$, $r^2 = 0.981$) have further confirmed the culture-derived relation of Prahl et al. (1988) (Müller et al., 1998) and demonstrated its applicability to most oceanic areas (Figure 1). Though slight differences exist in the U^k_{37} -temperature dependence of different coccolithophorid species and genetic variations (Conte et al., 1998), past changes in species composition do not appear to compromise paleo-SST reconstructions (Müller et al., 1997).

Most studies, including the core-top U^k_{37} -SST calibration of Müller et al. (1998), assume that U^k_{37} values reflect temperatures at the sea surface. However, alkenone concentrations in sediment traps indicate that the depth of maximum production varies regionally and can even change between different seasons. Alkenone-producing haptophytes show highest abundance in the surface mixed layer in the North Atlantic (Conte et al., 2001) and in the northwest Pacific (Hamanaka et al., 2000). Similarly, Ohkouchi et al. (1999) concluded from a sediment transect in the Pacific that alkenones are produced in the surface mixed layer at high and low latitudes, while thermocline production prevails at Mid-Latitudes. In the gyre region of the subtropical North Pacific, haptophyte growth is linked to the depth of the chlorophyll maximum, which can vary in depth throughout the year (Prahl et al., 2005). Alkenone production shows a strong seasonal cycle in most areas (Conte et al., 2001; Leduc et al., 2010; Prahl et al., 2005), but the unsaturation ratio preserved in the sediments predominantly reflects mean annual temperatures (Müller and Fischer, 2001; Prahl et al., 1993, 2005). In contrast, a strong summer

to fall bias in U^k_{37} -SST estimates is observed in cold, high-latitude regions of the ocean (Prah et al., 2010; Sikes and Volkman, 1993; Sikes et al., 2005; Ternois et al., 1998), suggesting that in some areas, regional U^k_{37} -SST calibrations better reproduce SSTs.

Alkenones have been found in sediments as old as the early Cretaceous (Brassell et al., 2004) and they have been used to reconstruct SSTs on time scales ranging from 10^3 – 10^6 years.

Figure 1 Global core-top calibration of U^k_{37} -derived SST versus overlying mean annual SST from Müller et al. (1998) ($SST = U^k_{37} - 0.044 / 0.033$, $r^2 = 0.958$).

Despite substantial alkenone loss in both the water column and the sediment after deposition, several studies indicate stability of the U^k_{37} -index over geologic time and, therefore, no effect on paleo-SST reconstructions (Conte et al., 1992; Müller and Fischer, 2001; Prah et al., 1989, 1993). However, contrasting studies indicate differential removal of $C_{37:3}$ (Gong and Hollander, 1999; Rontani et al., 2005, 2008), which can have implications for alkenone paleothermometry, depending on the conditions under which degradation occurred (e.g., anoxic, oxic, denitrifying). Other environmental factors potentially affecting the unsaturation ratio of alkenones include light limitation (causing a bias towards warmer SSTs) and nutrient limitation (bias towards lower SSTs; Prah et al., 2003).

The TEX_{86} and MBT/CBT Paleotemperature Proxies

Over the last decade, two new paleotemperature proxies were developed based upon the relative abundances of various glycerol dialkyl glycerol tetraethers (GDGTs) (Figure 2). Isoprenoidal GDGTs with *sn*-2,3 stereochemistry are produced by at least two of three main groups of archaea, the *Crenarchaeota* and the *Euryarchaeota* (De Rosa and Gambacorta, 1988; Koga and Morii, 2005), that occur ubiquitously in the environment, including in the open ocean (e.g., Karner et al., 2001), lakes (e.g., Powers et al., 2010), and soils (Leininger et al., 2006). *Crenarchaeota* biosynthesize different types of GDGTs containing 0–3 cyclopentane moieties (I–IV; Figure 2) and crenarchaeol (V), which, in addition to four cyclopentane moieties, has a cyclohexane ring (Schouten et al., 2000; Sinninghe Damsté

Figure 2 Base peak HPLC-MS chromatograms of GDGTs with the various structures indicated. (a) Sample from the Norwegian Drammensfjord, with a TEX_{86} value of 0.42 and a BIT index value of around 0.6. (b) Sample from the Arabian Sea, with a TEX_{86} value of 0.68 and a BIT index of <0.05. Reproduced from Schouten S, et al. (2009) An interlaboratory study of TEX_{86} and BIT analysis using high-performance liquid chromatography-mass spectrometry. *Geochemistry, Geophysics, Geosystems* 10: Q03012.

et al., 2002). They also synthesize small quantities of a regioisomer of crenarchaeol (V').

Other GDGTs have an *sn*-1,2 stereochemistry and *n*-alkyl chain architecture, and contain varying amounts of methyl branches and cyclopentane moieties (VI–VIII, Figure 2). The exact biological source of these so-called branched GDGTs remains uncertain. Initially attributed to soil bacteria (Herfort et al., 2006; Hopmans et al., 2004; Sinninghe Damsté et al., 2000; Weijers et al., 2006), they can also be produced, as suggested by recent evidence, in sediments or in the water column (Peterse et al., 2009a,b; Sinninghe Damsté et al., 2009; Tierney and Russell, 2009).

Culture studies have shown that the relative number of cyclopentane moieties in the GDGTs from hyperthermophilic archaea increases with growth temperature (Gliozzi et al., 1983) (Uda et al., 2001), which has been interpreted as a means by which archaea adjust their cell membrane rigidity. This dependency on growth temperature was also demonstrated for the nonhyperthermophilic archaea (Wuchter et al., 2004). Thus, by measuring the relative amounts of GDGTs present in marine sediments, the temperature at which *Crenarchaeota* were living when they produced their membranes can be determined. The TEX₈₆ proxy was proposed as a means to quantify the relative abundance of GDGTs (Schouten et al., 2002):

$$\text{TEX}_{86} = \frac{[\text{III}] + [\text{IV}] + [\text{V}]}{[\text{II}] + [\text{III}] + [\text{IV}] + [\text{V}]} \quad [1]$$

The roman numerals refer to structures in Figure 2. The original 44 sediment core-tops from 15 different locations used to establish this new paleotemperature proxy were expanded in the years that followed. Kim et al. (2008) analyzed 287 core-top sediments distributed over the world oceans from different depths, and after exclusion of samples from the Red Sea and the polar oceans, as well as another fifteen outliers, they arrived at the following global temperature calibration:

$$\text{SST} = -10.78 + 56.2 \times \text{TEX}_{86} \quad (r^2 = 0.935, n = 223) \quad [2]$$

Two years later, Kim et al. (2010) expanded this dataset again to 426 core-tops, and proposed a new calibration:

$$\text{SST} = 67.5 \times \text{TEX}_{86}^L + 46.9 \quad (r^2 = 0.86, n = 396, p < 0.0001) \quad [3]$$

with

$$\text{TEX}_{86}^L = \log \left(\frac{[\text{III}]}{[\text{II}] + [\text{III}] + [\text{IV}]} \right) \quad [4]$$

Besides being logarithmic, this new calibration excludes the regioisomer of crenarchaeol (structure V'). It appears better suited to colder temperatures (<15 °C) including those of the polar oceans. For temperatures >15 °C, Kim et al. (2010) proposed a logarithmic calibration based on the original TEX₈₆ proxy:

$$\text{SST} = 68.4 \times \log \text{TEX}_{86} + 38.6 \quad (r^2 = 0.87, n = 255, p < 0.0001) \quad [5]$$

The TEX₈₆ temperature proxy has also been shown to work in large lakes characterized by high *Crenarchaeota* production (Powers et al., 2010). They proposed the following modified TEX₈₆ calibration specifically for lakes:

$$\text{LST} = -14.0 \times \text{TEX}_{86} + 55.2 \quad [6]$$

This calibration varies only slightly from the 'original' marine calibration (eqn [2]), suggesting that salinity does not have a large effect on the TEX₈₆ proxy, a conclusion also reached by Wuchter et al. (2004) based on mesocosm experiments.

The TEX₈₆ SST proxy has been primarily applied in open ocean studies, where the confounding influence of terrestrially sourced GDGTs is minimized. Examples are late Quaternary water temperature reconstructions from the Arabian Sea (Huguet et al., 2006b), the African lakes (Tierney et al., 2008), the Mediterranean Sea (Castañeda et al., 2010), the Eocene Arctic Ocean (Brinkhuis et al., 2006; Sluijs et al., 2006), and the Cretaceous proto-Atlantic (Schouten et al., 2003).

Several limitations and potential confounding influences must be considered when applying and interpreting TEX₈₆-based temperature reconstructions. Several studies (Wakeham et al., 2003; Wuchter et al., 2005, 2006) have shown that, even though archaea live throughout the water column and hence produce GDGTs at a variety of depths (Herndl et al., 2005; Ingalls et al., 2006; Karner et al., 2001), sedimentary TEX₈₆ values typically reflect the SST of water layers <100 m deep. This is likely due to the efficient export of organic matter from the surface ocean in the form of aggregates and zooplankton fecal pellets (Huguet et al., 2006a). This is, however, not always the case, and sedimentary GDGTs can reflect the average temperature of the entire water column (Menzel et al., 2006). Another potential source of uncertainty is the seasonally varying production of GDGTs (e.g. Leider et al., 2010; Sinninghe Damsté et al., 2009; Wuchter et al., 2005) though sediment core-top TEX₈₆ values do appear to reflect mean annual temperatures (Kim et al., 2008). This is likely the result of seasonally invariant archaeal growth and export. Oxidation of GDGTs under prolonged oxic conditions, such as can occur in turbidites deposited in the deep ocean, can also lead to changes in TEX₈₆ values equivalent to 2–6 °C (Huguet et al., 2009). The relative abundance of *Crenarchaeota* versus *Euryarchaeota* or even different *Crenarchaeota* populations that may produce different relative abundances of GDGTs can also influence TEX₈₆-based SSTs (Schouten et al., 2008; Turich et al., 2007, 2008). This is particularly likely in coastal, lacustrine, or isolated basins (Trommer et al., 2009) as well as in upwelling areas (Lee et al., 2008), where certain strains of *Crenarchaeota* and *Euryarchaeota* might be favored. In anoxic settings, such as highly organic-rich sediments and anoxic basins, methanotrophic archaea may also be a significant source of GDGTs to sediments (Blaga et al., 2009; Sinninghe Damsté et al., 2009; Wakeham et al., 2004).

Besides the branched GDGTs, soil organic matter also typically contains some of the isoprenoidal GDGTs I, II, and III and some crenarchaeol. A significant contribution of these GDGTs prohibits the use of the TEX₈₆ proxy; this can be evaluated using the branched versus isoprenoid tetraether (BIT) index:

$$\text{BIT} = \frac{[\text{VI}] + [\text{VII}] + [\text{VIII}]}{[\text{V}] + [\text{VI}] + [\text{VII}] + [\text{VIII}]} \quad [7]$$

Values above 0.3 may be used as a general limit, although evaluation of the terrestrial and marine end-members is recommended when possible (Weijers et al., 2006). Because of this

complication, the TEX₈₆ cannot be used in many coastal settings and in most lakes (Blaga et al., 2009; Powers et al., 2004, 2010).

The distribution patterns of branched GDGTs have also been explored for their utility as paleoenvironmental proxies. The relative amount of cyclopentane moieties (VI–VIIIb and c, Figure 2), expressed as the CBT index, was found to be related to the pH of the soil, while the relative amount of methyl branches, expressed as the MBT, was positively correlated with the annual mean air temperature and, to a lesser extent, to soil pH (Peterse et al., 2009b; Weijers et al., 2007).

$$\text{CBT} = -\log \left(\frac{[\text{VIIb}] + [\text{VIIIb}]}{[\text{VII}] + [\text{VIII}]} \right) \quad [8]$$

MBT=

$$\frac{[\text{VIII}] + [\text{VIIIa}] + [\text{VIIIb}]}{[\text{VI}] + [\text{VII}] + [\text{VIII}] + [\text{VIa}] + [\text{VIIa}] + [\text{VIIIa}] + [\text{VIb}] + [\text{VIIb}] + [\text{VIIIb}]} \quad [9]$$

$$\text{CBT} = 3.33 - 0.38 \times \text{pH} (r^2 = 0.70, n = 134) \quad [10]$$

$$\text{MBT} = 0.867 - 0.096 \times \text{pH} + 0.021 \times \text{MAT} (r^2 = 0.82, n = 134) \quad [11]$$

The latter two equations can be combined:

$$\text{MBT} = 0.122 - 0.187 \times \text{CBT} + 0.020 \times \text{MAT} (r^2 = 0.77) \quad [12]$$

One example of the use of this proxy is the reconstruction of East Asian continental temperatures during the last deglaciation period (Peterse et al., 2010).

Biomarker Proxies of Salinity

Along with temperature, salinity is the most important oceanographic parameter. Its reconstruction can shed light on changes in ocean stratification, water mass circulation, and precipitation, which are tightly linked to climate. Recent developments in organic geochemistry have produced two promising paleosalinity proxies: the relative abundance of tetraunsaturated C₃₇ methyl ketones (alkenones) and the hydrogen isotopic composition (D/H) of organic compounds produced by phytoplankton and plants.

The %C_{37:4} Paleosalinity Proxy

The C_{37:4} alkenone is produced primarily in cold surface waters of the ocean (temperatures <10 °C) (Rosell-Melé et al., 1994) and is not well preserved in sediments compared to the di- and triunsaturated alkenones. It is, therefore, most often excluded from alkenone paleotemperature reconstructions (see the

section ‘Alkenone Paleothermometry’). In polar regions, however, the inclusion of C_{37:4} into the unsaturation ratio (U_k³⁷) can, in some cases, increase its correlation with SST (Bendle and Rosell-Melé, 2004).

At concentrations of %C_{37:4} (relative abundance of C_{37:4} to the total abundance of C_{37:2}, C_{37:3}, and C_{37:4}, as percentage) >5%, the temperature relation breaks down (Rosell-Melé, 1998; Sicre et al., 2002; Sikes et al., 1997), however, and a correlation with salinity has, instead, been suggested in the Nordic Seas and the North Atlantic (Rosell-Melé, 1998; Rosell-Melé et al., 2002; Sicre et al., 2002; Table 1). A %C_{37:4}-salinity dependence was also observed in the low-salinity waters of the Sea of Okhotsk (Seki, 2005), the Bering Strait (Harada et al., 2003), and the Baltic Sea (Blanz et al., 2005; Schulz et al., 2000; Table 1), leading to the suggestion that low salinities may impose stress on the alkenone-producing haptophytes, causing them to increase production of C_{37:4} (Harada et al., 2003).

The established %C_{37:4}-salinity relations, however, vary significantly between oceanic regions (Table 1), and no correlation with salinity was found in particulate and surface sediment samples from the Nordic Seas (Bendle et al., 2005) or the Atlantic, Pacific, and Indian sectors of the Southern Ocean (Sikes and Sicre, 2002). The applicability of %C_{37:4} as a salinity proxy may thus be restricted to certain cold, low-salinity marine environments. Further studies will need to establish whether this is due to a possible contribution to C_{37:4} production from other environmental factors. Nevertheless, the importance of establishing past salinity variations justifies this further work.

The Lipid δD Paleosalinity Proxy

The hydrogen isotopic composition ($\delta D = [(D/H)_{\text{sample}} / (D/H)_{\text{standard}} - 1] \times 1000$), where the standard is Vienna Standard Mean Ocean Water of lipids from plants and algae reflect the δD value of environmental water (Englebrecht and Sachs, 2005; Sachse et al., 2004; Sauer et al., 2001; Sessions et al., 1999; Zhang and Sachs, 2007). Precipitation δD values, in turn, reflect air temperature, air mass trajectory, intensity of precipitation, and the isotopic composition of source water. Temperature tends to dominate at high latitudes, while precipitation intensity tends to dominate in the tropics, such that lower precipitation δD values occur at lower temperatures and higher precipitation intensities (Dansgaard, 1964). Since most hydrogen in lipids is bound to carbon and, therefore, nonexchangeable on time scales of millions of years, the δD value of sedimentary lipids contains important information on past hydrological conditions and climate.

δD values in alkenones have been shown in culture and field studies to closely record the isotopic composition of the

Table 1 %C_{37:4}-Salinity relationships in different ocean basins

Ocean basin	Linear regression	R ²	Reference
North Atlantic and Nordic Seas	%C _{37:4} = 146.9(±10.6) – 4.1S (±0.3)	0.69	Rosell-Melé et al. (2002), p. 1301
North Atlantic	%C _{37:4} = 48.1S + 1691	0.78	Sicre et al. (2002), p. 1304
Bering Strait	%C _{37:4} = 11.7S + 397.6	0.76	Harada et al. (2003), p. 1310

water in which they were produced (Englebrecht and Sachs, 2005). Alkenone δD values are depleted relative to that of the water by some -193‰ (Englebrecht and Sachs, 2005), reflecting the initial deuterium depletion of the primary photosynthate of -171‰ (Yakir and DeNiro, 1990) and further fractionation during alkenone biosynthesis. A greater D depletion of $C_{37:3}$ relative to $C_{37:2}$ requires chromatographic separation of the individual alkenones prior to isotope analysis (D'Andrea et al., 2007; Schwab and Sachs, 2009). Moreover, different hydrogen isotope fractionation by the two most abundant producers of alkenones in the modern ocean, *E. huxleyi* and *Gephyrocapsa oceanica* (δD offset $\sim 30\text{‰}$; Schouten et al., 2006), requires knowledge of the species distribution and their temporal changes for robust paleoceanographic reconstructions based upon alkenone δD values.

D/H fractionation during the biosynthesis of alkenones and a wide variety of other phytoplanktonic and cyanobacterial lipids has been recently shown to occur in response to salinity changes (Schouten et al., 2006; Sachse and Sachs, 2008; Sachs and Schwab, 2011). D/H fractionation decreased by an average of $0.9 \pm 0.2\text{‰}$ per unit ($\sim \text{ppt}$) increase in salinity in a variety of lipids from hypersaline ponds on Christmas Island in the tropical Pacific Ocean (Sachse and Sachs, 2008) and in the dinoflagellate sterol dinosterol from the Chesapeake Bay estuary in the eastern United States (Sachs and Schwab, 2011) (Figure 3). This response to salinity is most often additive to the effect of the δD value of the environmental water, in which arid conditions result in higher evaporation relative to precipitation, and, therefore, higher water δD values and vice versa. This increases the sensitivity of biomarker δD as a salinity proxy for the quantitative reconstruction of past changes in the hydrological cycle.

The lipid δD paleosalinity proxy has been applied to reconstruct salinity variations in late Quaternary ocean sediments (Pahnke et al., 2007; van der Meer et al., 2007) and from late

Holocene sediments in the Black Sea (van der Meer et al., 2008) and from saline lakes on tropical Pacific islands (Sachs et al., 2009; Smittenberg et al., 2011).

There is still much we do not understand about the environmental influences on D/H fractionation during lipid synthesis in phytoplankton and cyanobacteria. In addition to salinity, recent work indicates that growth rate, growth phase, and growth temperature, all seem to influence D/H fractionation in phytoplankton (Wolhowe et al., 2009; Zhang et al., 2009). But these effects may be small in comparison to the water δD and salinity effect in many settings.

The Highly Branched Isoprenoid Sea Ice Proxy (IP₂₅)

C_{25} and C_{30} highly branched isoprenoid (HBI) alkenes are ubiquitous components in recent sediments that appear to originate from four genera of marine diatoms (Class Bacillariophyceae), *Rhizosolenia*, *Haslea*, *Navicula*, and *Pleurosigma* (Grossi et al., 2004). Several C_{25} HBI alkenes ($C_{25:1}$ to $C_{25:6}$) have been characterized in cultures of *Haslea* and *Pleurosigma* (Wraige et al., 1997).

The reported covariance of numbers of unsaturations in HBI alkenes in diatoms with temperature once represented a hopeful new paleotemperature proxy (Rowland et al., 2001). However, this proxy has not been successfully applied to paleotemperature reconstructions.

Recently, a unique C_{25} monounsaturated HBI has been detected in sea ice samples. Some *Haslea* species have been reported to inhabit Arctic sea ice (Booth and Horner, 1998). The recent sediments from the Arctic with this C_{25} monounsaturated HBI underlie either seasonal or permanent ice cover, and it has yet to be reported in sediments from more temperate environments or from northern high-latitude open-water or ice-free phytoplankton (Belt et al., 2007). As a result, the

Figure 3 Fractionation factors for a variety of lipids from hypersaline ponds on Christmas Island (Sachse and Sachs, 2008) and the Chesapeake Bay estuary (Sachs and Schwab, 2011). The average slope of all regressions is 0.0009 ± 0.0002 , implying a relatively constant decrease in D/H fractionation of 0.9‰ per unit increase in salinity.

monounsaturated isomer has been attributed to sea ice diatoms, and its existence in sediments is an indicator of sea ice. The proxy has been named IP25 (ice proxy with 25 carbons) (Belt et al., 2007).

The IP25 records from sediments have proven to be remarkably consistent with historical sea ice records and with other paleoclimatic parameters (Gregory et al., 2010; Massé et al., 2008). The $\delta^{13}\text{C}$ values of IP25 in sea ice and in sediment trap material collected under sea ice are also distinguishably heavier than that of organic matter from planktonic or terrigenous sources, supporting the use of IP25 as an Arctic sea ice proxy (Belt et al., 2008).

IP25 has been applied for the reconstruction of sea ice over the last several centuries (Vare et al., 2010) and during the last 30 000 years (Müller et al., 2009).

Summary

Tremendous progress has been made in the last decade developing and applying organic geochemical indicators of past climate. A small set of the most significant of these advances has been reviewed here. Advances in analytical chemistry in the coming years ought to make all of the temperature and hydrologic proxies described here available to a broad range of geochemists. The different biological, physical, and chemical underpinnings of these proxies, as compared to the inorganic paleoclimate proxies widely used today, such as the oxygen and carbon isotopes and trace metal ratios in foraminiferal shells, make them complementary. In some climatic or depositional environments, one or another of the temperature or hydrologic proxies may work best, while in other settings it ought to be possible to apply two or more indicators of the same climate parameter within a single sediment core. As a result, increasingly robust reconstructions of climate are certain to emerge.

Coccolithophores

J-A Flores and F J Sierro, Universidad de Salamanca, Salamanca, Spain

© 2013 Elsevier B.V. All rights reserved.

Introduction

Coccolithophores are unicellular, autotrophic organisms belonging to the marine phytoplankton that during certain phases of their cycle of life are able to produce calcium carbonate plates called coccoliths. In consequence, they are included in the more general term calcareous nannoplankton. Cell size in general is lower than 30 μm , and their reproduction is mainly by binary division (mitotic), although in several cases, more complex processes are observed. Once the cell has died, the coccosphere descends to the sea floor, constituting one of the most important contributors to the oceanic sediments since the late Triassic (Figure 1).

Their habitat is restricted to the upper part of the water column with a wide latitudinal range extending from the polar regions to the tropics. Owing to their great abundance and the existing relationship between photosynthesis and calcification, coccolithophores are a key element in the biochemical cycles of the Earth. Blooms of these algae are observed today, covering large regions of the ocean that can be monitored by satellite imagery (Figure 2).

The use of coccolithophores as paleoclimatic and paleoceanographic indicators needs precise knowledge of their biology and ecology. Culture experiments are completed with the recovery of living assemblages in different oceans, as well as annual and seasonal records in sediment traps, providing valuable information about their behavior. Additionally, the relationship between the coccolithophore assemblages and environmental parameters, such as surface water temperature or nutrient contents, makes it possible to use them as paleoceanographic proxies in the sedimentary material recovered by coring, drilling, or in continental outcrops.

The abundance and regularity of these organisms in the oceanic sediment record, as well as their relatively high rate of evolutionary divergence, confers important biostratigraphic value to this group.

Biology

Included in the Division Haptophyta (Table 1), coccolithophores are characterized by having a golden-brown chloroplast and, in most observed living species (with a motile phase), a flagella system. A third element, called haptonema, is sometimes observed between the long regular flagella (Figure 3). The secretion of scales takes place in the vicinity of the Golgi body, and these calcify inside the cell to produce a coccolith (in most cases calcitic) that finally occupies the cell periphery. The function of these plates is not well understood, but probably they serve to protect the cell against grazers and viruses or as a tool to control the light absorbed by the cell. The morphology of coccoliths and the structure and organization of their crystalline units are the

criteria used for their classification (Figure 4). The orientation of the crystal units produces an interference figure when observed under the cross-polarized light of a petrographic microscope, and their individual patterns of interference are diagnostic at the species level (Green and Leadbeater, 1994; Haq, 1983; Haq and Boersma, 1978; Tappan, 1981; Thierstein and Young, 2004; Winter and Siesser, 1994; Young et al., 1997).

Three major types of coccoliths can be distinguished (Figure 4; Young et al., 2003):

Heterococcoliths: These are characterized by calcitic units of varying shapes and sizes and ordered in cycles. Their generation is intracellular and seems to occur in most cases during the diploid phase (Figures 4 and 5).

Holococcoliths: These are characterized by small crystal units organized in circular or oval aggregates. The calcification seems to be extracellular during the haploid phase (Figures 3 and 4).

Nannoliths: Calcitic plates different from the hetero- and holococcoliths are grouped under this classification. In general, they correspond to simple crystal structures that originally occupied internal or external positions in the cell, formed under different biomineralization processes, and may include, in some cases, forms not linked to coccolithophores (Figures 5 and 6).

In most cultivated species, the dominant mechanism of reproduction is asexual by binary division (mitotic); each new cell shares the coccoliths previously generated by its parents. However, in other cases, including some of the most abundant taxa (e.g., *Emiliania huxleyi*, *Helicosphaera carteri*, and *Coccolithus pelagicus*), a more complex cycle is observed. The succession of diploid ($2n$) and haploid (n) phases generates heterococcolith and holococcoliths (plus organic scales), respectively. The origin of nannoliths is diverse and is not well known at present (Figure 6).

The most common and diverse types are heterococcoliths. Three main morphological types have been distinguished, although these types are not taxonomically significant (Figure 6; Young et al., 2003):

Placolith: A disc-shaped coccolith with two shields connected by a tube

Murolith: A bowl-shape coccolith with a dilated central area bounded by a wall of variable height

Planolith: A disc-shaped coccolith with a single shield

Modifications of these generic types at the periphery (circular, elliptical, or polygonal), or the presence of bars, spines, or stems are the criteria used for taxonomy.

Both the reproductive mechanisms and the morphology of some taxa seem to be linked to environmental features, opening new possibilities to explore their use as tracers.

Ecology

As autotrophic (photosynthesizing) organisms that live in the uppermost part of the water column (photic zone), light intensity is the main limiting factor for coccolithophore proliferation (Figure 7). Other factors, such as temperature, nutrient contents or salinity, as well as competition with other organisms, also control their distribution. It is difficult to consider these factors separately because they interact continuously with each other and with the physicochemical properties of water masses, such as upwelling, stratification, and turbidity.

Light and Temperature

Luminosity directly affects the development and characteristics of coccolithophore assemblages. This parameter, however, must be considered from different points of view: first, latitudinal

Figure 1 Coccospheres of *Emiliana huxleyi* (a) and *Helicosphaera carteri* (b). Photo courtesy of Lluisa Cros.

control, due to differences in the intensity of solar radiance, as well as in the seasonal (annual and daily) cycles; second, water-depth control, related to the differential absorption of wavelengths. These factors are closely related to sea-surface temperature, which also has a latitudinal and water-depth gradient (Thierstein and Young, 2004; Winter and Siesser, 1994).

Light penetration and seasonality

The progressive attenuation of light in the water column, as a consequence of the absorption of different wavelengths, affects coccolithophore assemblages. Most species live in the upper photic zone (UPZ; 100–10% of light), corresponding to the first 50 m (Figure 7). A reduced number of species are specialized to use low wavelength light (blue and violet) and grow in the middle and lower photic zone (MPZ and LPZ; less than 1% of light), which may reach 200 m water depth. This is the case of *Oolithotus* spp. and *Florisphaera profunda*, inhabitants of the MPZ and LPZ, respectively (low light intensity at shallower depths may be caused by an increase in turbidity due to high terrigenous sedimentation, the presence of volcanic ash, or excess biological production, causing an increase in organisms normally living in the LPZ in the UPZ). As with light intensity, temperature also decreases with depth and, as a result, LPZ inhabitants grow in a colder environment in any given latitude (Figure 7).

Latitude

In general terms, coccolithophores are widespread in the ocean, extending from the tropics with temperatures over 28 °C, as in the Gulf of Mexico, to the cold waters in the Pacific sector of the Southern Ocean, with temperatures around 2 °C. Day length, combined with low temperature, is the factor

Figure 2 Coccolithophore bloom (light green) in the North Atlantic, close to France and United Kingdom. Provided by the SeaWiFS Project, NASA/Goddard Space Flight Center, and ORBIMAGE (<http://oceancolor.gsfc.nasa.gov/>).

affecting coccolithophore assemblages in high latitudes, where the assemblages include only a few euryhaline and eurythermal (cosmopolitan) species. Toward lower latitudes, assemblages become more diverse, with more specialized populations.

Traditionally, different biogeographic regions have been recognized from the Arctic to the Antarctic oceans, related to the most extensive surface water masses: subantarctic, temperate (or transitional), subtropical (central), tropical (equatorial), and subantarctic (Figure 8). Each biogeographic zone is characterized by a coccolithophore assemblage, where cosmopolitan species live together with other geographically restricted forms (McIntyre and Bè, 1967).

This is, however, a simplistic picture that only provides a general idea about coccolithophore distribution; particular features, such as eddies, upwelling regions, or closed basins, are not considered, and coccolithophore assemblages in these environments may be significantly different. On the other hand, there is

Figure 6 Structure and morphology of (a) heterococcoliths, (b) holococcoliths, and (c) nannoliths. Modified from Young JR, Geisen M, Cros L, et al. (2003) Special Issue: A guide to extant coccolithophore taxonomy. *Journal of Nannoplankton Research* 1: 1–125, Photo courtesy of José Gravalosa.

a significant degree of hemispheric and ocean provincialism, which is especially patent in the distribution of some species, and this can introduce noteworthy modifications.

Nutrients

As part of the marine phytoplankton, the availability of bio-limiting nutrients, such as phosphorus and nitrogen (in the form of phosphates and nitrates), is fundamental for

coccolithophore development and diversification. Both nutrients act directly on cellular constitution and calcification, but in environments with high nutrient concentrations, as in the case of upwellings, the proliferation of other organisms (e.g., diatoms that are better adapted to proliferating in these scenarios) competes with that of coccolithophores, limiting their growth. The phytoplankton community responds to increasing levels of nutrient availability following a biological succession (Margalef, 1978) that has been defined as follows

Figure 8 Biogeographic zonation for the Atlantic and Pacific oceans. Modified from McIntyre A and Bé AWH (1967) Modern Coccolithophoridae of the Atlantic Ocean I: Placoliths and Cyrtoliths. *Deep-Sea Research* 14: 561–597.

(Figure 8): in regimes of high turbulence and high nutrient contents (eutrophic), diatoms are the dominant organisms; coccolithophores are also abundant, developing an r-selected ecological strategy (opportunistic; growth rate maximized). In contrast, under conditions of low-turbulence and low-nutrient contents (oligotrophic), dinoflagellates are proportionally more abundant. In between these conditions (mesotrophic), coccolithophores are, in relative terms, the most abundant organisms, developing a k-selected ecological strategy (specialist; efficiency maximized). Biological succession is a generic concept that explains a general behavior, but particular aspects, such as physiological characteristics of some organisms or local variations, have not yet been considered in the issue. Furthermore, it is important to consider that, in the absence of strong competition, environments with high nutrient contents favor the production of all organisms, and the succession occurs when some of the nutrients become depleted, or are present in low proportions (e.g., Si, for diatoms), but nitrates are abundant (Figure 9).

In this succession, two particular situations are interesting: one is the high nutrient concentration scenario in low-turbulence regimes that elicits red tides (by dinoflagellates). The second situation occurs in low-turbulence regimes, with moderate-to-low nutrient contents; to this, a third factor should be added: long day length, causing coccolithophore blooms. This phenomenon is well known in *Emiliana huxleyi*, which produces spectacular blooms that can even be observed from space (Figure 2). Similar mechanisms persisting over time can be invoked to explain the high concentration of species morphologically similar to *Emiliana huxleyi* in the middle and late Pleistocene, such as those observed for the 'small' *Gephyrocapsa* (<3 μm) and *Gephyrocapsa caribbeana* (Figure 10).

In conclusion, the abundance and characteristics of coccolithophore assemblages are directly linked to the stability of the mixed layer (turbulence), the nutrient content, and light penetration. The thickness of the mixed layer in the ocean

Figure 9 Relationship between organisms, nutrients, and turbulence: biological succession. The behavior of coccolithophores is considered generically; some species can respond in different ways. Coccolithophore blooms are referred to *Emiliana huxleyi* (Balch, 2004). Modified from Margalef R (1978) Life-forms of phytoplankton as survival alternatives in an unstable environment. *Oceanologica Acta* 1: 493–509.

Figure 10 Petrographic microscope photography of *Gephyrocapsa caribbeana* (ODP Site 1089) Atlantic Ocean, during MIS 11.

determines the position of the thermocline (pycnocline), which is also linked to the nutricline (depth of maximum rate of change in the concentration of nutrients). The position of the nutricline in the water column controls the coccolithophore assemblage: a deep nutricline situated in the LPZ, in accordance with a stratified and stable oceanic environment, is characterized by the dominance of LPZ coccolithophore species. Alternatively, a shallow thermocline (and nutricline) is consistent with the development of a UPZ coccolithophore assemblage. The quantification of these nanoflora can be used to reconstruct past variations in the position of those parameters, which in turn have been controlled by atmospheric dynamics (Molfinio and McIntyre, 1990).

Three main groups of coccolithophores can be distinguished, based on the stability of oceanic environments (Figure 7; Okada and Honjo, 1973; Winter and Siesser, 1994):

1. The placolith-bearing assemblage dominates eu- and mesotrophic environments. Small cells (e.g., *Emiliania huxleyi*) are relatively more abundant in upwelling regimes, whereas large cells (e.g., *Calcidiscus*, *Umbilicosphaera*...) are more frequent in the open-ocean, in mid-latitudes.
2. The umbelliform assemblage is characteristic of oligotrophic regimes, especially in subtropical gyres. This assemblage occurs with large placolith-bearing and abundant discoliths and muroliths (e.g., *Pontosphaera*, *Rhabdosphaera*, or *Syracosphaera*).
3. The floriform assemblage, abundant in low and mid-latitudes, occupies the LPZ (*Florisphaera profunda*) and MPZ (*Oolithotus fragilis*, not properly a floriform species).

Although some of these assemblages have latitudinal restrictions, an estimation of their ratios can be used to monitor past oceanographic changes.

Coccolith Production and Accumulation Mechanisms

Around 60% of the total oceanic calcium carbonate comes from coccoliths. The production of these plates (see the section 'Biology') is linked to photosynthesis, which provides the energy required to transport inorganic carbon and calcium inside the cell according to the expressions:

During this process, CO_2 is released. However, the generation of organic matter involves the absorption of CO_2 , according to:

Figure 11 summarizes the existing relationship between production of organic matter and calcium carbonate precipitated by coccolithophores. The uptake of Ca for shell construction and of CO_2 for the generation of cellular and skeletal matter controls the coccolithophore $\text{CaCO}_3/\text{C}_{\text{org}}$ rain ratio.

As shown by the equations (Figure 11), coccolith production affects the concentration of CO_2 . The production of organic matter takes up CO_2 (the organic carbon pump), while the production of calcium carbonate releases CO_2 (carbonate pump). The sinking coccoliths remove organic carbon and

Figure 11 Relationship between processes of production and dissolution of calcium carbonate and coccolithophore action.

carbonate carbon from the surface ocean in a proportion of approximately 5:1 (Corg/CaCO₃), termed the rain ratio.

Once cells have died, disaggregated coccospheres descend through the water column. In theory, in a quiet environment without lateral water movements, the sinking rate of coccolith-sized particles of about 3 µm is estimated at 14 cm per day, implying hundreds of years to reach the sea floor. However, coccoliths are affected by two processes that considerably increase their sedimentation rate (Figure 11). First, grazers ingest high amounts of coccolithophores, which, after digestion, are expelled as fecal pellets, reaching a critical mass that increases their sedimentation rate; in addition, some of these pellets form an organic capsule that protects coccoliths from corrosive deep waters (Honjo, 1976). Second, 'marine snow' (the continuous shower of mostly organic detritus that falls through the water column) agglutinates organic and inorganic particles to form high-density aggregates that reach the sea floor at rates close to 200 m per day (Thierstein and Young, 2004).

Although carbonate dissolution occurs at all depths, it is especially significant after the first thousand meters. The carbonate ion concentration ([CO₃²⁻]) is larger in the sea surface and decreases with water depth. This pattern, combined with the temperature and pressure dependence of the saturation concentration, results in the upper ocean being everywhere supersaturated, and the deep ocean being progressively undersaturated with increasing water depth. Calcium carbonate dissolves when waters are subsaturated in calcite or aragonite. The water depth at which calcite subsaturation starts is called the calcite lysocline, while aragonite subsaturation usually occurs at much shallower depths. Below the calcite lysocline, carbonate shells and fragments are still present in the sediments, but calcite dissolution is complete at the calcite compensation depth (CCD). During sedimentation, coccoliths are affected by dissolution, especially if they sink in subsaturated waters. The effect of these waters depends on the length of time the coccoliths remain in contact with the corrosive waters, the effectiveness of protection systems (e.g., pellets), and the coccolith structure. Rapid sedimentation and burial prevent (or at least diminish) dissolution, whereas coccoliths constituted by large crystals are more resistant than those formed by small structures.

Holococcoliths are easily dissolved forms, while heterococcoliths (with large elements) and monocrystalline nannoliths are the most resistant. The study of coccolith dissolution is a potential tool, not much used, to monitor past variations in the CCD. Taking into account that calcium carbonate dissolution is linked to atmospheric, oceanic, and biosphere dynamics, monitoring dissolution can help to understand global processes such as CO₂ variability in the global system (Thierstein and Young, 2004).

Large regions of the sea floor are covered by nannofossil oozes, where the coccolith (or nannofossils, coccolithophore-related fossil organisms) concentration constitutes over 90% of the sediment. In other lithologies, coccoliths are diluted by terrigenous or other biogenic components. Their absence or low abundance in deep-ocean sediments (for mid- and low latitudes) is usually related to dissolution or winnowing processes. The persistence of bottom currents over biogenic sediments can produce the loss of tiny forms (coccoliths) and the enrichment of coarse microfossils (e.g., planktonic foraminifers). The winnowing of the small size forms favors the

remobilization and ultimate creation of an allochthonous assemblage, causing changes in the original coccolithophore biocenosis (biological community). Consequently, a preliminary evaluation of these factors is crucial to understanding the sedimentary record. Additionally, paleoceanographic studies are based on direct comparisons between present-day data recovered from living assemblages or from sediment traps affected by seasonality, and on the coccolithophores from surface sediments. Most authors agree that in the absence of dissolution, reworking or mixing, the surface sediment records mean annual values.

In addition to the particular significance of certain species and their potential for monitoring variations in productivity, a direct correlation between the coccolithophore accumulation rate and productivity proxies can be observed. In oceanic settings not affected by dissolution, the coccolithophore accumulation rate is a good proxy for paleoproductivity (Flores et al., 2003).

Coccolithophores as Paleoceanographic Indicators

The study of coccolithophores in sediment cores provides useful information about the location of surface water masses. Modification of the assemblages and the geochemical composition of the shell by environmental features such as SST, distribution, and nutrient abundance, and the relationship of these with oceanic and atmospheric processes, is the basis for using coccolithophores as paleoceanographic proxies. Even though coccoliths are abundant in the sedimentary record, this group has been little used for paleoceanographic reconstructions. The cosmopolitanism of the most abundant species, as well as their rapid evolutionary trends, prevents the application of actualistic methods. Curiously, however, this explains their success in biostratigraphy (Bown, 1998).

Reconstruction of Latitudinal Variations and Temperatures

In a general sense, global climatic changes are manifested in the ocean as variations in the position of front-limiting surface water masses, which, as discussed above, have their characteristic coccolithophore assemblages. The identification of these assemblages in the sedimentary sequence allows past spatial changes in these fronts to be monitored. One of the first attempts was made in the North Atlantic, in an attempt to trace the northward movement of the polar front over the last 20 000 years (McIntyre, 1967): Subarctic assemblages were found in sediment cores at latitudes between 42° and 45° N, marking the southernmost penetration of the north polar front during glacial periods. This simple technique permitted an orbital-related signal to be identified that was consistent with glacial–interglacial pulses of different intensities. However, the availability of high-resolution sedimentary records has shown that coccolithophores can help detect abrupt and short-term rapid changes in SST. Figure 12 shows the results obtained in a sediment core from the western Mediterranean, where Heinrich and Dansgaard–Oeschger stadial cold events were detected using the cold water morphotype of *Emiliania huxleyi* (>4 µm; Colmenero-Hidalgo et al., 2004; Sierro et al., 2005).

With the improvement of biogeographic referential patterns, as well as the advent of new data about the behavior of

Figure 13 Down-core paleotemperature obtained in ODP Site 1233 situated in the NE coast of South America by a coccolithophore transfer function, and its comparison with results obtained with biogeochemical and micropaleontological techniques. Reproduced from Saavedra-Pellitero M, Flores JA, Lamy F, Sierro FJ, Cortina A (2010) Coccolithophore estimates of paleotemperature and paleoproductivity changes in the Southeast Pacific over the past ~27 ka. *Paleoceanography*, <http://dx.doi.org/10.1029/2009PA001824>.

as a paleoproductivity proxy, useful in the reconstruction of Pleistocene sequences (Stoll et al., 2002).

Oceanic productivity is related to the characteristics of the water masses and the ability of the ocean in this region to distribute nutrients in the photic layer. A stable stratified

system, such as in subtropical gyres, is coherent with a deep thermocline/nutricline, favoring the development of inhabitants of the LPZ. The opposite scenario occurs in upwelling regions, with a narrow mixed layer and a shallow nutricline, where the UPZ inhabitants are the dominant forms. According to this pattern, the ratio between LPZ and UPZ offers the possibility of monitoring fluctuations in the position of the thermocline (Molfino and McIntyre, 1990). Additionally, comparisons with present-day data allow the development of transfer functions to estimate paleoproductivity and the position of the thermocline, which in turn is related to wind intensity and direction. Application of this technique in the equatorial Indian and Pacific oceans has led to the identification of precessional-controlled variations in the position of the thermocline, linked to ENSO oscillations for the last climatic cycle. A deep nutricline is associated with frequent El Niño-like scenarios during interglacials, whereas intervals of high productivity correspond to a shallow (and/or a lower gradient) nutricline during glacials. It has been demonstrated that this oscillation is directly controlled by insolation and is independent of global ice volume variations (Beaufort et al., 2001).

Carbon isotope values may be used for fertility reconstructions in the ocean. Preliminary $\delta^{13}\text{C}$ values measured in coccoliths seem to reflect the seawater composition, and consequently surface water productivity, although additional studies are needed and should be applied in sediment series. Recently, other geochemical proxies, such as the Sr/Ca ratio, have been carried out using coccoliths. This ratio is considered a good indicator of surface water fertility when applied to monospecific samples of *Emiliania huxleyi* (Stoll et al., 2002).

How Do Coccolithophores Affect the Climate System?

As primary producers, coccolithophores are important contributors to the biological pump that removes CO_2 from surface ocean waters; however, they also remove significant amounts of calcium carbonate. Calcite burial and dissolution in deep-sea sediments have important impacts on the CO_2 cycle. The balance between organic matter and calcium carbonate production determines the $\text{CaCO}_3/\text{C}_{\text{org}}$ rain ratio, a parameter that can be used to estimate the effectiveness of the process (Fischer and Wefer, 1999). A high accumulation of calcium carbonate in sediments contributes to increase the relative proportion of CO_2 that, as stated above, can be balanced by a high production of organic matter in surface waters (CO_2 consuming). This process also depends on the contribution of other planktonic organisms (e.g., diatoms and foraminifers).

During the Pleistocene, episodes of high coccolith production have been recognized, such as one reconstructed for the warm interglacial episode of MIS 11. At that time, a single species, such as the small but robust placolith *Gephyrocapsa caribbeanica*, was dominant in the ocean (Figures 10 and 15) (Bollmann et al., 1998; Flores et al., 2003). These episodes of inferred high coccolith production are coincident with intense dissolution at the deepest regions of the sea floor and a rising CCD.

Figure 14 Relationship between total accumulation rate of coccolithophores (NAR = nannofossils accumulation rate) and some paleoproductivity proxies (P/Ti and Sr/Ti) in ODP Site 1089 (Atlantic Southern Ocean), for the last 500 kys. T represents terminations, and MIS marine isotope stages (Flores and Filippelli, unpublished).

Additionally, coccolithophores, like other phytoplanktonic organisms, are producers of dimethyl sulfide (DMS). When released to the air, this compound is the primary source of the sulfur particles that stimulate the formation of clouds. An increase in cloud formation by enhanced DMS emission can cause an increase in the albedo (the Earth's reflectivity) which can affect the climate system (Thierstein and Young, 2004). Further studies on this topic, both in present-day and past environments, are needed.

Pleistocene Biostratigraphy and Biochronology

Age control is the first step in any paleoceanographic study. Geochronological, geomagnetic, and geochemical techniques currently provide the main framework for obtaining time-reference points. However, sometimes, these techniques are time consuming and are not always easy to apply (e.g., in routine studies in oceanographic vessels), and alternative techniques such as biochronology (identification of time-calibrated biological events) are needed. Coccolithophores (and biologically related calcareous nannofossils) are an abundant

and widespread oceanic micropaleontological group, with a high evolutionary rate that generates identifiable changes in taxa and in assemblages, which are easy to identify using petrographic and electron microscopy techniques. These characteristics have played a key role in the success of the group in biostratigraphy (Figure 15).

Standard biostratigraphic patterns are restricted, offering low-resolution solutions. Over the last decade, exhaustive studies have allowed the identification of different events, calibrated by comparison with geomagnetic and oxygen isotope (orbital) time scales. The parallel correlation of biostratigraphic, paleomagnetic, and isotope events allows us to evaluate whether or not they occurred synchronously in different regions, together with their relationship with environmental parameters (Wei, 1993; Raffi, 2002; Colmenero-Hidalgo, 2004; Flores et al., 2003; Raffi et al., 2006).

As already discussed, coccolithophore assemblages are latitudinally controlled, and hence, this may limit the usefulness of some events for global correlations. In addition, some species, morphotypes, or assemblage characteristics may be different in particular regions or oceanic settings, such as in upwelling or restricted basins, and a general pattern is difficult to apply.

Figure 15 Compilation of the most significant biostratigraphic coccolithophore events and their geochronological calibration. Glossary

δ : Standard reporting notation for light stable isotopes is delta (δ) notation. Delta values are calculated using the equation $(R_{\text{sample}}/R_{\text{standard}} - 1) \times 1000$, where R is the ratio of the heavy to light isotope (e.g., $^{18}\text{O}/^{16}\text{O}$).

‰: Standard unit of delta (δ) notation is per mil (‰; per thousand).

$\Delta^{14}\text{C}$: Standard reporting notation for radiocarbon (^{14}C) content, which is expressed as the per mil deviation from the $^{14}\text{C}/^{12}\text{C}$ ratio in 19th-century wood. Units are ‰.

$^{14}\text{C}_{\text{AMS}}$: Radiocarbon age determinations made using accelerator mass spectrometric techniques.

Introduction

The early identification and understanding of the temporal significance of growth increments in many calcareous skeletons, but especially those in mollusks and corals, facilitated their use as a means to study environmental variability in the Quaternary. Armed with this understanding, geochemical studies of the skeletons of mollusks and corals, and later of sclerosponges, began in earnest. These early investigations established many of the fundamental principles that now form the foundation of nearly all studies using the skeletons of corals, sclerosponges, and mollusks to study environmental and climate change. In this article, we provide a general overview of the use of corals, sclerosponges, and mollusks as archives of variability in the Quaternary Earth system.

Corals

Scleractinian or stony star corals belong to the subclass Zoantharia (Hexacorallia), in the class Anthozoa of the phylum Cnidaria. Scleractinia are polyp animals found exclusively in marine environments, which first appeared in the middle Triassic (~240 Ma). Scleractinians include solitary and colonial forms, many of which secrete a hard calcareous (aragonite) exoskeleton that provides support and protection for the polyps. Scleractinian corals form two ecological groups: reef builders (hermatypic) and non-reef builders (ahermatypic). Hermatypic corals, the best-known scleractinia, contain symbiotic dinoflagellates (autotrophic zooxanthellae) and inhabit shallow waters of the tropical oceans where they secrete massive, calcium carbonate skeletons that, along with calcareous algae, form the physical structure of coral reefs. Ahermatypic corals lack symbiotic algae (azooxanthellae) and hence are not restricted to shallow waters; they inhabit all regions of the ocean.

The corallite is the central macroarchitectural component of the aragonite skeleton of corals, as each corallite houses a polyp animal. A corallite may be thought of as a calcareous tube with vertical walls (theca), radiating vertical partitions

(septa), and horizontal layers (dissepiments) at the base of the coral polyp. As the surface of the corallite extends, new dissepiments are formed higher in the theca and old dissepiments are abandoned as the polyp raises itself up its theca. The living tissue, which is the site of calcification, occupies only a small fraction of the coral exoskeleton. Coral growth includes elongation (lengthening of the skeleton over time by extension) and thickening (mass addition of the skeleton over time). The interplay between extension and thickening results in variations in skeletal density and produces annual density bands in most hermatypic corals.

Quaternary environmental reconstructions using ahermatypic corals are in their nascent phase and hold great promise; however, the bulk of the literature is based on studies of massive hermatypic corals and this article will focus on these shallow-water corals. Optimal growth conditions for hermatypic corals include warm, shallow, and protected water (20–26 °C; 5–15 m), low sediment load, and normal ocean salinity. Massive corals are exceptional archives of late Quaternary environmental change in the tropics because: (1) they can be precisely dated (U-series; radiocarbon annual growth increments), (2) they are long-lived (tens to hundreds of years), (3) the geochemistry of their aragonite skeletons provides a record of temperature and salinity variations, and (4) the ecological distribution of some species permit robust reconstruction of sea level elevation. Corals that have proven particularly useful in Quaternary environmental reconstructions include massive *Porites* sp. corals from the Indo-Pacific, massive *Montastraea* sp. from the Atlantic, and to a somewhat lesser extent *Diploria* sp. from the Atlantic.

Patterns of annual density banding reflect variations in a number of environmental variables (e.g., temperature, water quality, light conditions, nutrient availability). These variations may be used to retrospectively monitor growth characteristics of massive corals and infer past environmental changes. The most commonly reported growth variable is linear extension rate, which can vary considerably within and between genera and individual coral colonies from the same reef. As an example, annual average extension rates vary from ~13 mm yr⁻¹ in massive *Porites* corals from the Great Barrier

Reef (GBR), to $\sim 8 \text{ mm yr}^{-1}$ in massive *Montastraea* corals from the Florida Keys, to $\sim 4 \text{ mm yr}^{-1}$ in massive *Diploria* corals from Bermuda. Early and subsequent work on growth variations in Bermuda corals demonstrated a link between skeletal extension and temperature and air pressure. Researchers in Australia have generated multicentury length skeletal extension records from a multitude of *Porites* heads from the GBR, Australia, and they have demonstrated that linear extension and calcification rates were significantly and directly correlated with latitudinal variations in average sea surface temperature. Ongoing work on growth variations in corals from the Caribbean and Gulf of Mexico holds significant promise.

A diverse record of environmental variability is also encoded into the geochemistry of the aragonite skeleton of massive, hermatypic corals. The vast majority of geochemical records generated over the years from corals have been stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotopes. Early, seminal work demonstrated kinetic and metabolic fractionation results in the precipitation of coralline aragonite that is not in isotopic equilibrium with ambient seawater. The degree of isotopic disequilibrium differs amongst the different coral genera, with corals having lower $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values than inorganic aragonite precipitated from the same fluid as coralline aragonite. Despite this isotopic disequilibrium, which likely reflects biological mediation of the fluid involved in precipitation, a multitude of studies over the years have demonstrated that robust records of environmental variability can be constructed using stable isotopic variations in coralline aragonite, provided that the skeleton is properly sampled.

The $\delta^{18}\text{O}$ of coralline aragonite is primarily influenced by the sea surface temperature (SST) and $\delta^{18}\text{O}$ composition of seawater during skeletal precipitation. There is an inverse relation between coral $\delta^{18}\text{O}$ and temperature, such that when temperature increases, coral $\delta^{18}\text{O}$ values become more negative. The slope of the $\delta^{18}\text{O}_{\text{coral}}$ -SST relationship has been estimated by various workers to range from 0.18‰ per $^{\circ}\text{C}$ to 0.22‰ per $^{\circ}\text{C}^{-1}$, which is close to that determined in inorganic aragonite. Variations in $\delta^{18}\text{O}_{\text{seawater}}$ reflect changes in the volume of water stored in continental ice sheets and changes in the hydrologic balance (evaporation and precipitation). Increases (decreases) in continental ice volume result in increases (decreases) in $\delta^{18}\text{O}_{\text{seawater}}$. Precipitation (evaporation) results in decreases (increases) in $\delta^{18}\text{O}_{\text{seawater}}$. Time series of coral $\delta^{18}\text{O}$ variations, many of which have subannual resolution, have played a critical role in extending the instrumental record of tropical climate variability on timescales of seasons, years, decades, and centuries. These records have been used to constrain past behavior of coupled ocean-atmosphere systems including the Asian monsoon, the El Niño-Southern Oscillation (ENSO), Pacific Decadal Oscillation (PDO), and North Atlantic Oscillation (NAO). Coral $\delta^{18}\text{O}$ records have also been instrumental in understanding the behavior of the tropical climate system during times of changes in background climate states (e.g., glacial states).

Coral $\delta^{13}\text{C}$ variations have proven more difficult to interpret in terms of environmental variability. Skeletal $\delta^{13}\text{C}$ values reflect the two main carbon sources for corals: dissolved inorganic carbon (DIC) in seawater and zooplankton. Variations in skeletal $\delta^{13}\text{C}$ values reflect some combination of metabolic activities within the tissue layer (respiration and photosynthesis) and

heterotrophy (the consumption of other organisms). Environmental factors postulated to drive variations in skeletal $\delta^{13}\text{C}$ include light levels (as modulated by water depth, cloud cover, and/or seasonality), dietary changes (heterotrophy vs. autotrophy), and changes in seawater DIC.

The radiocarbon ($\Delta^{14}\text{C}$) in coral skeletons closely matches that of surrounding seawater DIC and coral $\Delta^{14}\text{C}$ records reflect changes in ocean circulation patterns and processes on all timescales, which are often driven by changes in climate (e.g., ENSO). The classical application of coral radiocarbon is the study of ocean circulation, which takes advantage of differences between surface and deep-water radiocarbon values to study vertical mixing and differences in the radiocarbon values of different source regions to study surface advection.

Variations in element-to-calcium ratios (e.g., Sr/Ca, Mg/Ca, U/Ca, Ba/Ca, Cd/Ca) in coral skeletons have also been used to reconstruct environmental variability, with various degrees of success. Coral Ba/Ca variations have been demonstrated to reflect changes in riverine input and upwelling in reef sequences of the GBR and the Galapagos, respectively. Coral Pb/Ca variations in a Bermuda coral record industrial pollution from the east coast of North America through Pb/Ca variations. A great deal of effort has been put forth in attempts to establish elemental ratio-based coral thermometer; U/Ca, Mg/Ca and Sr/Ca have been proposed. Most workers in the field agree that factors other than temperature affect coral U/Ca and Mg/Ca variations, which confounds their use as coral thermometers. Coral Sr/Ca is a most widely applied coral thermometer, although its use as a thermometer is not without critics. Coral Sr/Ca varies in response to changes in seawater temperature and seawater Sr/Ca. Many workers have argued for the constancy of seawater Sr/Ca on millennial timescales, based on residence time considerations; other workers have argued for variations in seawater Sr/Ca in the modern ocean based on select measurements. Some workers have argued for a strong biological control on coral Sr/Ca; whereas others have produced reproducible records of Sr/Ca from multiple coral heads, variations which have strong coherency with known climate phenomena such as ENSO and PDO.

Coral Sr/Ca determinations, when paired with coral $\delta^{18}\text{O}$ determinations made from the same sample, offer promise as a means to isolate the thermal and hydrologic components of the signal. The temperature component of the coral $\delta^{18}\text{O}$ is resolved using coral Sr/Ca, leaving a residual $\delta^{18}\text{O}$ record, which should reflect changes in seawater $\delta^{18}\text{O}$. Several of these coral-based, residual or calculated seawater $\delta^{18}\text{O}$ records have been produced. Some extend back several centuries and suggest that significant and sometimes abrupt changes in the hydrologic regime of the tropics was far more prevalent than previously thought.

Sclerosponges

Sclerosponges, also referred to as coralline sponges, are marine organisms with a dense skeleton that is primarily calcareous, with minor amount of siliceous spicules. Sclerosponges are calcified demosponges (Phylum Porifera) with a long geologic history, extending from the late Cambrian to the present. Fifteen species of sclerosponges, some of which are extinct,

have been identified, which belong to 2 classes, 4 subclasses, 8 families, and 11 genera. Sclerosponges have proven particularly useful in environmental reconstructions in the Quaternary: *Ceratoporella nicholsoni*, the most massive Caribbean sclerosponge with an aragonite skeleton, and *Astrosclera willleyana* (aragonite) and *Acanthochaetes wellsi* (calcite), which are widely distributed and abundant sponges in the Indo-Pacific. Sclerosponges tend to inhabit cryptic (i.e., sheltered) environments. *Ceratoporella nicholsoni* are common in deeper sections of fore reef as well as light-starved submarine caves, and *A. willleyana* and *A. wellsi* are common in well-flushed, sublit-toral caves in reef walls.

Sclerosponges are thought to build their skeleton in a manner analogous to scleractinian corals, in which the porous upper portion of the skeleton houses the living organism and the dense lower skeleton is devoid of living sponge tissue. Calcification occurs within the living tissue layer, and is characterized by extension in the uppermost region of the tissue layer and thickening in the lower regions. The two-stage calcification process results in time averaging of the environmental signal, the magnitude of which is a function of tissue layer thickness, growth rate, and density difference between the porous upper skeleton and dense basal skeleton. The basal skeleton of sclerosponges is very dense, approaching that of solid aragonite (2.93 g cm^{-3}), and denser than the aragonite skeletons of reef-building corals. Hence, sclerosponges are thought to be less susceptible to postdepositional alteration than corals.

Sclerosponges are slow-growing, long-lived organisms; average growth rates range from 0.1 to 0.3 mm yr^{-1} as estimated using staining (Alizarin Red-S, Calcein) and/or radiometric techniques (^{14}C , ^{210}Pb , U-Th). Recent work suggests growth rates can reach 1.2 mm yr^{-1} in *A. wellsi*. The internal chronology of sclerosponges has been constrained using ratios of Sr/Ca (*C. nicholsoni*) and $\delta^{13}\text{C}$ (*A. wellsi*), which have been shown to respond to seasonal temperature changes. Growth rates within a single sponge can deviate from the average growth rate by a factor of 2 using such high-resolution techniques; however, the mean growth rate is similar to constant growth rate estimates. Such methods have been proposed to provide high-resolution age models for cross-correlation in time of sclerosponges from different locations for paleoclimate studies, much the same way that coral sclerochronology is often made more precise using geochemical signals. In *C. nicholsoni* the overall slow growth rate indicates that even small sponges may live for hundreds to thousands of years. Sclerosponges do not have annual density bands, unlike scleractinian corals, but the skeletons of some species do contain concentric bands of darker material. The chronologic significance of such color variations is still being investigated. Sclerosponge skeletons contain relatively high uranium and low thorium concentrations, making them amenable to absolute dating with high precision via mass spectrometric U-series techniques. Sclerosponges skeletons are also amenable to radiocarbon age determinations.

The combination of slow growth rates, long life spans, depth distribution in the upper water column, and amenability to absolute dating make sclerosponges particularly attractive as an archive of Quaternary climate variations. Pioneering early work on sclerosponges concluded that these sponges precipitate their aragonite skeleton at (near?) stable isotopic

equilibrium with ambient seawater, a determination that has been confirmed by subsequent studies. Such equilibrium precipitation is an attribute that distinguishes them from reef-building corals.

Carbon isotopic records in sclerosponges have played a seminal role in providing independent evidence for the influence of deforestation and fossil-fuel burning on the $\delta^{13}\text{C}$ of DIC in surface seawater (i.e., Suess effect). These records exhibit significant and reproducible depletions in $\delta^{13}\text{C}$, as first documented in records from the Caribbean and then in those from the Indo-Pacific. The highly reproducible nature of the twentieth century trend toward more depleted $\delta^{13}\text{C}$ values in sclerosponge $\delta^{13}\text{C}$ records provides additional chronological constraints in proxy records using sclerosponges. In detail, sclerosponge $\delta^{13}\text{C}$ records vary from region to region, reflecting the local surface seawater DIC, the variability of which is a function of oceanic carbon cycling.

Oxygen isotopic values determined from skeletons of sclerosponges agree with the expected isotopic equilibrium values for ambient seawater temperature and $\delta^{18}\text{O}$ composition, although detailed calibration studies of the sclerosponge $\delta^{18}\text{O}$ -temperature relationship, like those performed for scleractinian corals, are in their infancy. Initial relationships between $\delta^{18}\text{O}$ and temperature have been based on bulk oxygen isotope values and annual average temperatures from seven sclerosponges, and these results match the biogenic aragonite line over a small temperature range. This similarity facilitates direct comparison between $\delta^{18}\text{O}$ records among different sedimentary archives. Records of $\delta^{18}\text{O}$ from sclerosponges having a depth distribution have also been combined with $\delta^{18}\text{O}$ records from surface-dwelling corals to document variations in thermocline depth.

Variations in elemental concentrations (e.g., Pb) in sclerosponges have shown to reflect environmental variability. For example, in Caribbean and Bahamas sclerosponges, there are sharp increases in Pb concentrations from the post-1850 industrial period, which coincide with increases in Pb concentrations documented in Greenland snow and a scleractinian coral from the Florida Keys. Differences in the shape of the Pb peak have been demonstrated at different depths from the same location and between different locations, most likely a result of differences in particulate settling. Nonetheless, the Pb peak in sclerosponges is very pronounced and can be used as another age constraint.

The concentrations of boron, magnesium, and barium are lower in sclerosponges relative to those in scleractinian corals, whereas concentrations of strontium and uranium are significantly higher in sclerosponges. Such differences likely reflect differences in calcification mechanisms between the non-zooxanthellate sclerosponges and the zooxanthellate corals. Element-to-calcium ratios (e.g., Sr/Ca, U/Ca, B/Ca, Mg/Ca) in sclerosponges have recently been evaluated in terms of their utility as proxies of environmental change. The emerging consensus is that sclerosponge Sr/Ca holds the most promise as a proxy for changes in seawater temperature. The temperature sensitivity of Sr/Ca ratios in sclerosponges appears to be greater than in both inorganic aragonite and scleractinian coral skeletons. Such heightened temperature sensitivity is significant because of the small amplitude of the seawater temperature signal below the surface mixed layer.

Mollusks

During >500 Myr of evolution, mollusks (Phylum Mollusca) have occupied an extraordinarily broad variety of different ecological niches ranging from deep-sea to shallow-water habitats, from the poles to the equator, from lakes, rivers, and intertidal zones to dry land. Whereas all seven extant mollusk classes (Aplacophora, Monoplacophora, Polyplacophora, Scaphopoda, Bivalvia, Gastropoda, and Cephalopoda) occur in the marine realm, bivalves and gastropods also inhabit brackish and freshwater environments. Some snails even live in habitats on dry land. This enormous biogeographic distribution is uncontested in the animal kingdom.

Most mollusks form calcareous hard tissues that serve a multitude of different tasks (e.g., providing shape, stability, and protection). In addition, mollusk shells, particularly those of bivalves, fulfill the prerequisites of Quaternary climate archives because they function as precise calendars and record environmental information, in chronological order, during their entire life.

Mollusk shells grow by periodic accretion of skeletal material (mineral phase plus soluble and insoluble organic matrices) along the ventral margin. Precipitation of calcium carbonate from the pallial fluid is mediated by proteins. This process is periodically retarded or interrupted and results in the formation of distinct growth lines: zones enriched in organic material and characterized by different crystallization patterns (smaller crystallites, different growth direction, etc.). Growth lines segment the growth pattern into time slices of equal duration, so-called growth increments. Numerous studies have identified annual, fortnightly, daily, and ultradian (more than once a day) growth increments in mollusk shells reflecting cycles in temperature and food availability or other environmental variables, biological clocks (circadian/diurnal and circalunidian/tidal rhythms), or chemical cycles. Regular growth patterns can be used for a variety of different purposes, such as precise calendar dating of each shell portion, to estimate the time interval represented by samples taken from the shell for geochemical studies, to reconstruct life history traits and past environmental and climate changes or to determine the ontogenetic age of each specimen. The study of growth pattern analysis of molluscan shells is commonly known as mollusk sclerochronology.

In contrast to many ephemeral mollusk species that live only for a few years, some bivalves can live for many centuries, thereby adding less than $10\text{--}100\ \mu\text{m}$ of $\text{CaCO}_3\ \text{yr}^{-1}$ to their shells during gerontic stages. In fact, bivalves lead the list of the longest-lived animals that produce distinct incremental growth patterns in their hard parts. Examples are geoducks, *Panopea abrupta* (Conrad) from the Northwest Pacific (>160 yr old; ca. 15 cm shell width) or the freshwater pearl mussel, *Margaritifera margaritifera* (Linnaeus) from Scandinavian rivers (>300 yr; ca. 10 cm shell width). The ocean quahog, *Arctica islandica* (Linnaeus) from the North Atlantic can live for more than 375 yr and attains a shell height of less than 8 cm. Sclerochronological age estimates were substantiated by mark-and-recovery experiments (Tetracycline, Calcein, or Alizarin Red-S staining), absolute dating techniques ($^{14}\text{C}_{\text{AMS}}$, amino acid racemization), and cyclic variations of geochemical properties

in annual growth increments reflecting the seasonal temperature or primary productivity cycle.

Mollusk shells reliably record changes of the ambient environment as variable growth rates and variable geochemical properties. Usually, mollusk shells grow at faster rates (broader increments) at optimal growth conditions, for example, higher temperature, food availability, and food quality. Extraction of environmental signals from growth increment chronologies, however, requires removal of growth trends that are related to physiological aging. With increasing ontogenetic age, the absolute growth rate and the year-to-year variance (heteroscedasticity) decrease. These 'age' trends can be estimated and removed from the growth increment time series using detrending and standardizing techniques developed by dendrochronologists. The resulting chronologies are dimensionless measures of shell growth expressed as standardized growth indices (SGI). Several studies demonstrated that contemporaneous specimens alive in the same habitat exhibit similar SGI chronologies, indicating that shell growth is actually controlled by external factors. Based on similar growth patterns, SGI time series of many individuals with overlapping life spans can thus be strung together to form long, uninterrupted chronologies, so-called master or composite chronologies. Master chronologies cover many mollusk generations and provide a record of environmental variation that affected all specimens alive at the same time and in the same habitat. For example, growth patterns of geoduck shells from the NW Pacific were used to reconstruct decadal-scale variability of ocean currents (PDO) during the last 150 yr. Freshwater pearl mussels from Scandinavia demonstrated that the number of extreme cold summers has significantly decreased since the early twentieth century. Ocean quahogs from around Iceland indicated that heat advection (which itself varies in strength on quasi-decadal periods of 12–14 yr) to northern latitudes was strongly reduced during the Little Ice Age.

Geochemical properties of mollusk shells provide another possibility for reconstructing past climates and environments. Shell oxygen and stable carbon isotopes have frequently been used to confirm the annual formation of shell material, to infer subseasonal and inter-annual changes of water temperature, primary productivity, and to provide further evidence for an anthropogenic increase of CO_2 in the ocean. For example, shells of *Phacosoma japonicum* (Reeve) from shell middens revealed that Japan was exposed to large swings of monsoon-related precipitation during the Holocene. Several studies have confirmed that mollusks form their shell in oxygen isotopic equilibrium with the ambient water. If the $\delta^{18}\text{O}$ value of the water is known, the temperature during formation of the shell can be estimated. For example, the inter-annual temperature variability of the Labrador Current during the late nineteenth and twentieth century was reconstructed through the analyses of shell $\delta^{18}\text{O}$ values of *Arctica islandica*.

However, other stable isotope ratios (e.g., $\delta^{13}\text{C}$), trace and minor elements or element-to-calcium ratios (Sr/Ca, Mg/Ca, Ba/Ca) of mollusk shells seem to exhibit significant "vital effects" (i.e., trends related to growth rate, metabolism and/or ontogenetic age). Some bivalves may also be fairly selective against certain trace and minor elements, which may pose

limits on using shells as environmental biomonitors (tracking pollution sources etc.). Several potential proxies of environmental variables are currently being evaluated, including $\delta^{44}\text{Ca}$ (temperature proxy), $\delta^{11}\text{B}$ (pH proxy), and molecules containing more than one rare isotope (e.g., $^{13}\text{C}^{18}\text{O}^{16}\text{O}$ in $\text{CaCO}_3 = \delta^{18}\text{O}_{\text{water}}$ -independent temperature proxy).

The combination of widespread occurrence in time and space, multiproxy archiving and temporal control (calendar alignment) make mollusks ideal archives of Quaternary climate and environmental variability. Fast-growing young shell portions provide unique paleoweather data and information about seasonal environmental extremes. Long-lived species, however, can open century-long windows in the climatic past and provide detailed information on decadal-scale climate variability. An integrated approach that combines sclerochronological and geochemical techniques provides the most powerful tool to separate environmental signals from ontogenetic age- and growth rate-related noise.

Summary

In this short article, we have presented a survey of decades worth of research in the establishment and application of using the skeletons of corals, sclerosponges, and mollusks as sedimentary archives of environmental variability in the Quaternary. The environmental and climate record encoded in the skeletons of these organisms provide a background in which to assess future climate change. Those interested in learning additional information on the topic of this chapter are encouraged to use the articles listed in the References section as a starting point and to then delve into the abundant and additional primary literature.

Introduction

Dinoflagellates are microscopic unicellular organisms occupying most aquatic environments, from freshwater bodies to the open ocean. Most dinoflagellates are planktonic and use their two flagella to swim in spiral-like motion, from which their name originates (from the Greek word *dinos* meaning whirling). In biological sciences, dinoflagellates receive special attention since they represent an important part of the net primary production in aquatic environments and because they are responsible for harmful algal blooms or red tides. In paleontology and Earth sciences, dinoflagellates also deserve our particular interest since they yield microfossils, which constitute good biostratigraphic markers of the Mesozoic and Cenozoic. They have been shown to be useful paleoecological indicators of changes in sea-surface waters.

The motile stage of dinoflagellates does not produce remains that preserve as fossils, but about 10–20% of species experience a cyst stage that do yield microfossils. These microfossils mostly consist of highly resistant organic-walled cysts, also called dinocysts, which can be routinely observed under optical microscope in palynological slides. Therefore, the fossil remains of dinoflagellates do not correspond to the vegetative stage of the cells, and the morphology of living and fossil forms may differ considerably (Figures 1 and 2). Living dinoflagellates were described by naturalists in the eighteenth century, but the affinities of microfossils related to dinoflagellates have only been known since the second half of the twentieth century. Most fossil dinoflagellate cysts described from the beginning of nineteenth century until the end of the twentieth century were associated with ‘hystrichospheres’ and believed to be the remineralized skeletons of algae. Important progress in the understanding of the status of dinoflagellate cysts in the living world was made during the 1960s. The in-depth morphological observations of [Evvitt \(1963\)](#) permitted the identification of structures relating the fossil organic-walled cysts with dinoflagellates. Moreover, the *in vitro* experiments by [Wall and Dale \(e.g., 1966, 1968\)](#) demonstrated the biological affinities of dinocysts and contributed to the documentation of the stages of the life cycle of many taxa (Table 1).

Since the 1970s, many studies have been undertaken to document the distribution of dinocysts on the sea floor. About one hundred Quaternary dinocyst species have been described to date. The dinocyst assemblages in surface sediment samples of the marine environment show a biogeographic distribution with distinct latitudinal gradients from the Arctic seas to the circum-Antarctic Ocean, demonstrating their dependence on temperature and sea-ice conditions (e.g., [de Vernal et al., 2008](#); [Rochon et al., 1999](#)). Dinocyst distribution patterns also reflect inshore to offshore gradients

that have been linked to salinity, productivity, and eutrophication (e.g., [Dale, 1996](#); [Marret and Zonneveld, 2003](#); [Radi and de Vernal, 2008](#)). Based on these observations, it is possible to discern relationships between dinocyst assemblages and sea-surface conditions, including temperature, salinity, sea-ice cover, productivity and trophic characteristics of the waters, and therefore to use dinocyst assemblages for qualitative or quantitative reconstruction of paleoceanographic conditions (e.g., [de Vernal et al., 2005, 2008](#); [Radi and de Vernal, 2008](#)).

In addition to organic-walled cysts or dinocysts, some dinoflagellate taxa yield calcareous microfossils generally associated with the cyst stage. Calcareous dinoflagellates appear to be abundant in oceanic sediments at middle to low latitudes, where they can be used as tracers of hydrographic conditions in the upper water column (e.g., [Vink, 2004](#)).

Here, we principally summarize information on dinoflagellates and their organic-walled cysts, which are studied within the field of marine palynology and currently used for paleoenvironmental investigation in Quaternary sciences.

Ecology of Dinoflagellates

Dinoflagellates live in various types of aquatic environments, including lakes, estuaries, epicontinental seas and oceans, from equatorial to polar latitudes (for a synthesis of the ecology of dinoflagellates, see [Taylor and Pollinger, 1987](#) or [Matthiessen et al., 2005](#)). However, most dinoflagellates are marine: a few thousand species are known from marine waters, whereas only a few hundred species are known to live in freshwater.

In the oceans, dinoflagellates seem to be particularly well adapted to neritic (nearshore) environments, including the estuaries, epicontinental seas, and continental shelves. This is probably due to their broad tolerance to low salinity conditions, in addition to nutrient availability and stratification of water masses. In general, the diversity of dinoflagellates in surface waters increases toward the equator and decreases toward the poles.

The feeding strategy of dinoflagellates is variable. Many are autotrophic (i.e., photosynthetic) and form an important part of the planktonic primary production in lakes and oceans. About half of dinoflagellate species are heterotrophic or mixotrophic (i.e., feeding on other organisms or on dissolved organic substances), and others are symbionts of marine invertebrates such as corals in which they are known as zooxanthellae. The autotrophic dinoflagellates depend upon light and nutrients (notably nitrogen and phosphorus). They live in the photic zone at relatively shallow depths, usually within the upper 50–100 m. The heterotrophic dinoflagellates depend on the overall biological productivity of their environment

Figure 1 Photograph of *Gonyaulax* cyst and theca in optical microscopy (scale bar = 10 μm).

Figure 2 Scheme of dinoflagellate cyst and theca (*Gonyaulax*-type).

and generally live in surface waters where their prey can be found. Studies on feeding behaviors of dinoflagellates have also shown that several autotrophic species are actually mixotrophic, using either phagotrophy (engulfing particulates) or osmotrophy (assimilation of dissolved organic or inorganic compounds), possibly as a source of vitamins or to supplement their nutrition (e.g., Stoecker, 1999).

Dinoflagellates are mobile in the water column. They have two flagella, one around the cingulum and the other longitudinal, which permit swimming with a spiral-like 'whirling' motion with a speed ranging from a few centimeters to a few meters per hour. They use their flagella together with physiologic adjustment of buoyancy to migrate vertically in the water column, in order to optimize their metabolic and feeding activities. During the day, dinoflagellates migrate to the surface for photosynthesis, and during the night, they migrate down, away from the nutrient-depleted surface waters. Despite their ability to move vertically, dinoflagellates generally inhabit a relatively thin and shallow surface water layer, especially in stratified marine environments, because they cannot migrate across the pycnocline, an important physical barrier.

The reproduction of dinoflagellates is most commonly asexual by mitosis. In the blooming period, vegetative cell

divisions occur at a rate of about one per day. Sexual reproduction is also observed for many species. When blooming, dinoflagellates can be responsible for 'red tides,' so called because the large density of cells in the surface water induces a color change (green, brown, or red). Many dinoflagellates are bioluminescent and cause a glow at the sea surface by night. A few dinoflagellate species produce neurotoxins that may be bioconcentrated by filtering organisms, notably shellfish, which then become poisonous and dangerous for the health of animals (or people) that eat them.

In marine environments, dinoflagellates constitute one of the main primary producers, together with diatoms and coccolithophorids. Typically, dinoflagellates experience their blooms after diatoms.

The Life Cycle of Dinoflagellates and the Cyst Stage

Most dinoflagellates have a complex life cycle involving several stages: asexual and sexual, motile, and nonmotile (cf. Pfister and Anderson, 1987 for a synthesis, and Figure 3 for a schematic illustration). In general, during the course of sexual reproduction, the haploid vegetative cells ($1 - n$ chromosomes) become

or produce haploid gametes that fuse to develop a zygote. The zygote rapidly enters into a dormancy stage called 'hypnozygote,' during which the diploid cell (with $2 - n$ chromosomes) is protected by forming a cyst. After a dormancy period of variable length, the protoplasm excysts and meiosis occurs. The excystment of the cell occurs through an opening in the cyst called the

Figure 3 Schematic illustration of idealized dinoflagellate life cycle. Adapted from Evitt WR (1985) *Sporopollenin Dinoflagellate Cysts – Their Morphology and Interpretation*, 333 pp. Dallas, TX: American Association of Stratigraphic Palynologists Foundation.

archaeopyle, which has geometry determined by the morphology of the original theca (see Section ‘[The Taxonomy and General Morphology of Dinoflagellates and Dinocysts](#)’ below).

In the life cycle of dinoflagellates, the cysts have an extremely important function since they form a protective structure that fosters survival of the cell over long periods of time (several years to decades) and permits propagation and dispersal (cf. [Dale, 1983](#)).

The cyst wall of many species is made of highly resistant organic matter called dinosporin. This is similar in composition to the sporopollenin of pollen grains. These organic-walled cysts called ‘dinocysts’ are typically 15–100 μm in diameter. They are observed in palynological slides prepared following standard laboratory procedures used for the study of pollen and spores, which involve treatments with hydrofluoric and hydrochloric acids. The study of dinocysts is thus considered a subdiscipline of palynology.

Some dinoflagellates also produce cysts made of calcium carbonate, which fossilize in sediment. These are analyzed together with the calcareous nannoplankton. In addition to hypnozygotes, some dinoflagellates produce temporary cysts to survive adverse conditions. This type of cyst does not preserve as fossils.

There are variations in the life cycle of dinoflagellates. Sexual reproduction has been observed only in a few taxa, and more *in vitro* and *in vivo* studies are necessary for a comprehensive understanding of their life cycle. Only 10–20% of dinoflagellate taxa are known to produce cysts that preserve as fossils. The correspondence between the organic-walled or calcareous dinoflagellate cysts recovered

in sediments and their motile stage in the water column is known for several species but still needs to be established for many others.

The Taxonomy and General Morphology of Dinoflagellates and Dinocysts

Dinoflagellates are unicellular eukaryotic organisms that belong to the Protista, based on the classification system of five kingdoms. Because they include both autotrophic and heterotrophic species, dinoflagellates can be classified both by zoologists and botanists. Within the International Code of Zoological Nomenclature, they have been grouped under the phylum of Mastigophora. Dinoflagellates and their cysts, however, are more commonly treated as algae and are thus classified following the rules of the International Code of Botanical Nomenclature. For a long time, they have been associated to the division of Pyrrophyta named after the bioluminescent forms (from the Greek word *pyrrhos* meaning fire). Dinoflagellates are now grouped within the division of Dinoflagellata, which is distinguished on the bases of several criteria. A main one is the cell membrane that is characterized by a complex outer layer (the Amphiesma) containing a single layer of flattened vesicles (the amphiesmal vesicles). In the cases of many dinoflagellates, the amphiesmal vesicles contain thecal plates composed of cellulose. These dinoflagellates are classified as thecate, whereas those lacking such cellulosic plates are classified as naked or unarmored. Dinoflagellates also bear a unique

type of nucleus, the dinokaryon, which is characterized by chromosomes that remain condensed between cell divisions and which lack histones. Another peculiarity of dinoflagellates is their asymmetric morphology, and their possession of two dissimilar flagella.

The classification of dinoflagellates and their cysts is principally based on the structure of the Amphiesma and the organization of the thecal plates, referred to as tabulation. Among dinoflagellates producing cysts that have been recovered in Quaternary geological samples, three principal groups are represented: the Gymnodiniales that are unarmored and the Gonyaulales and Peridiniales that are thecate and show distinct types of tabulation (Figure 4).

In the Peridiniales and Gonyaulales, the tabulation pattern is described according to the organization of the theca from the apex to the cingulum and antapex, and according to the ventral or dorsal orientation. On the ventral (or sulcal) side, are inserted the flagella, whereas the archaeopyle is often located on the dorsal side of the cysts. The tabulation includes apical, precingular, cingular, postcingular, and antapical plates, which are labeled according to various systems (see Edwards, 1993; Evitt, 1985). The most commonly used is the Kofoid's system, based on the number of plates in each level of the theca. For the cyst stage, the prefix 'para' is used when referring to the outline of the plates on the cyst wall, and certain plates are called 'homologues' of their thecal counterpart. The tabulation system of Evitt and Taylor, which is based on the interconnection between plates, is also often used for the description and classification of Gonyaulales. The main morphological characteristic of Peridiniales is the presence of intercalary plates between the apical and precingular plate series on the dorsal side, which are lacking in Gonyaulales (Figure 5).

Independent classifications of dinoflagellates have been erected by biologists and paleontologists, and most of the literature of the nineteenth and twentieth centuries refers to distinct classification schemes for living and fossil dinoflagellates. Nevertheless, Fensome and colleagues (1993) made an attempt to reconcile the classification schemes by biologists and paleontologists, using various criteria (nucleus type, structure of the Amphiesma, tabulation) and proposed a common suprageneric classification for cyst and motile stages of dinoflagellates. At the generic and species levels, the motile stage name could be retained for both living and fossil forms for which the biological affinities of the cysts are known. However, these affinities are still uncertain for many Quaternary dinoflagellate cysts and for most pre-Quaternary ones. Therefore, the genera and species names given to dinocysts often differ from the ones of their living counterpart (cf. Head, 1996).

In the classification of living and fossil dinoflagellates, tabulation constitutes an important diagnostic character. The tabulation pattern of the dinoflagellates can be reflected in various ways in the cysts. Some dinocysts may show sutures or septa defining the original pattern of thecal plates. Others possess extensions called processes whose position may be determined by the original tabulation. Some do not show any evidence of tabular pattern, with the exception of the archaeopyle that has a given position. Beyond the tabulation patterns, as reflected by sutures or processes and from the archaeopyle, there are many morphological criteria used to distinguish and identify dinocyst species. They include the structure of the layers of the wall (cavate or proximate), the overall shape of the cyst (elongate, round, or flattened), the presence of apical or antapical horns, the presence of processes and sutures, their respective positions (following

tabulation or not), the ornamentation of the cyst wall, the size, the color (semitransparent or brown), etc. Explicit descriptions of the morphological nomenclature of dinocysts have notably been published by the [Groupe de travail 'Dinoflagellés' \(Dinoflagellate working group, 1986\)](#), [Head et al. \(1989\)](#), [Edwards \(1993\)](#).

The Organic-Walled Dinoflagellate Cysts or Dinocysts in the Marine Realm

Biostratigraphy of Dinocysts

Dinocysts are the most common organic-walled microfossils or palynomorphs in marine sediments. In the field of marine palynology, they have been intensively studied for biostratigraphic purposes, notably within the frame of petroleum exploration programs. The most ancient dinocysts known thus far date from the Silurian, but they are more abundant from the Triassic to the modern, with maximum diversity of species recorded during the Cretaceous and Paleogene (e.g., [Powell, 1992](#); for an exhaustive index of fossil dinoflagellate genera and species with their respective biostratigraphic ranges, see [Fensome and](#)

[Williams, 2004](#)). The diversity of species in the Quaternary sediments is relatively low, with close to hundred species formally described to date. Although it still needs investigation, the Pliocene and Quaternary biostratigraphic record of dinocysts shows extinctions of a few species and very rare first appearances of species (for North Atlantic biostratigraphic scheme see [de Vernal et al., 1992](#); [De Schepper and Head, 2008](#)).

Biogeographic Distribution of Dinocysts

Since the early work of [Wall et al. \(1977\)](#) documenting the modern distribution of dinocysts in sediments, many palynological studies have permitted the description of the distribution patterns of dinocysts on the sea floor. There are now regional data sets for the North Atlantic and the Arctic Ocean, the circum-Antarctic Ocean, the low latitudes of the Atlantic Ocean, and the eastern and western Pacific margins (see, e.g., the synthesis by [Rochon et al., 1999](#), the compilation by [Marret and Zonneveld, 2003](#), and the overview of [de Vernal and Marret, 2007](#)).

Studies providing indications of dinocyst abundance in sediments reveal high concentrations (up to 10^6 cysts cm^{-3}) along continental margins (shelves, inland seas, estuaries) and decreasing concentrations offshore, suggesting higher dinocyst fluxes in neritic (near shore) areas than in open oceans (Figure 6).

The species assemblages show large variations from the equator to the poles, with maximum species diversity at low latitudes. Many species appear ubiquitous or cosmopolitan and occur in wide latitudinal ranges of both hemispheres, but several appear to be restricted to equatorial–tropical environments. Only a few taxa seem to occur exclusively at polar and subpolar latitudes. Some species have been reported only

from the Northern Hemisphere, whereas others only occur in the Southern Ocean. Moreover, the species composition of assemblages apparently differs in the Atlantic and Pacific oceans. Thus, there is some regionalization in dinocyst distributions (Figures 7–13).

In general, the relative abundance of taxa in dinocyst assemblages follows distribution patterns closely related to the latitudinal and to nearshore-to-open-ocean gradients. Multivariate analyses of assemblages clearly demonstrate relationships with sea-surface temperatures, whatever the spatial scale being considered (e.g., Marret and Zonneveld, 2003; Radi and de Vernal, 2008). The analyses of assemblage distribution patterns at

Figure 6 Dinocyst concentration in surface sediment of the Northern Hemisphere (data updated from de Vernal et al., 2005 and Radi and de Vernal, 2008; see dinocyst databases at <http://www.geotop.ca>). The shaded light and dark blue areas correspond, respectively, to the median (1979–2000) of the minimum and maximum sea-ice extent (sea-ice data from the National Snow and Ice Data Center at <http://nsidc.org>). The isobaths correspond to water depths of 200 and 1000 m.

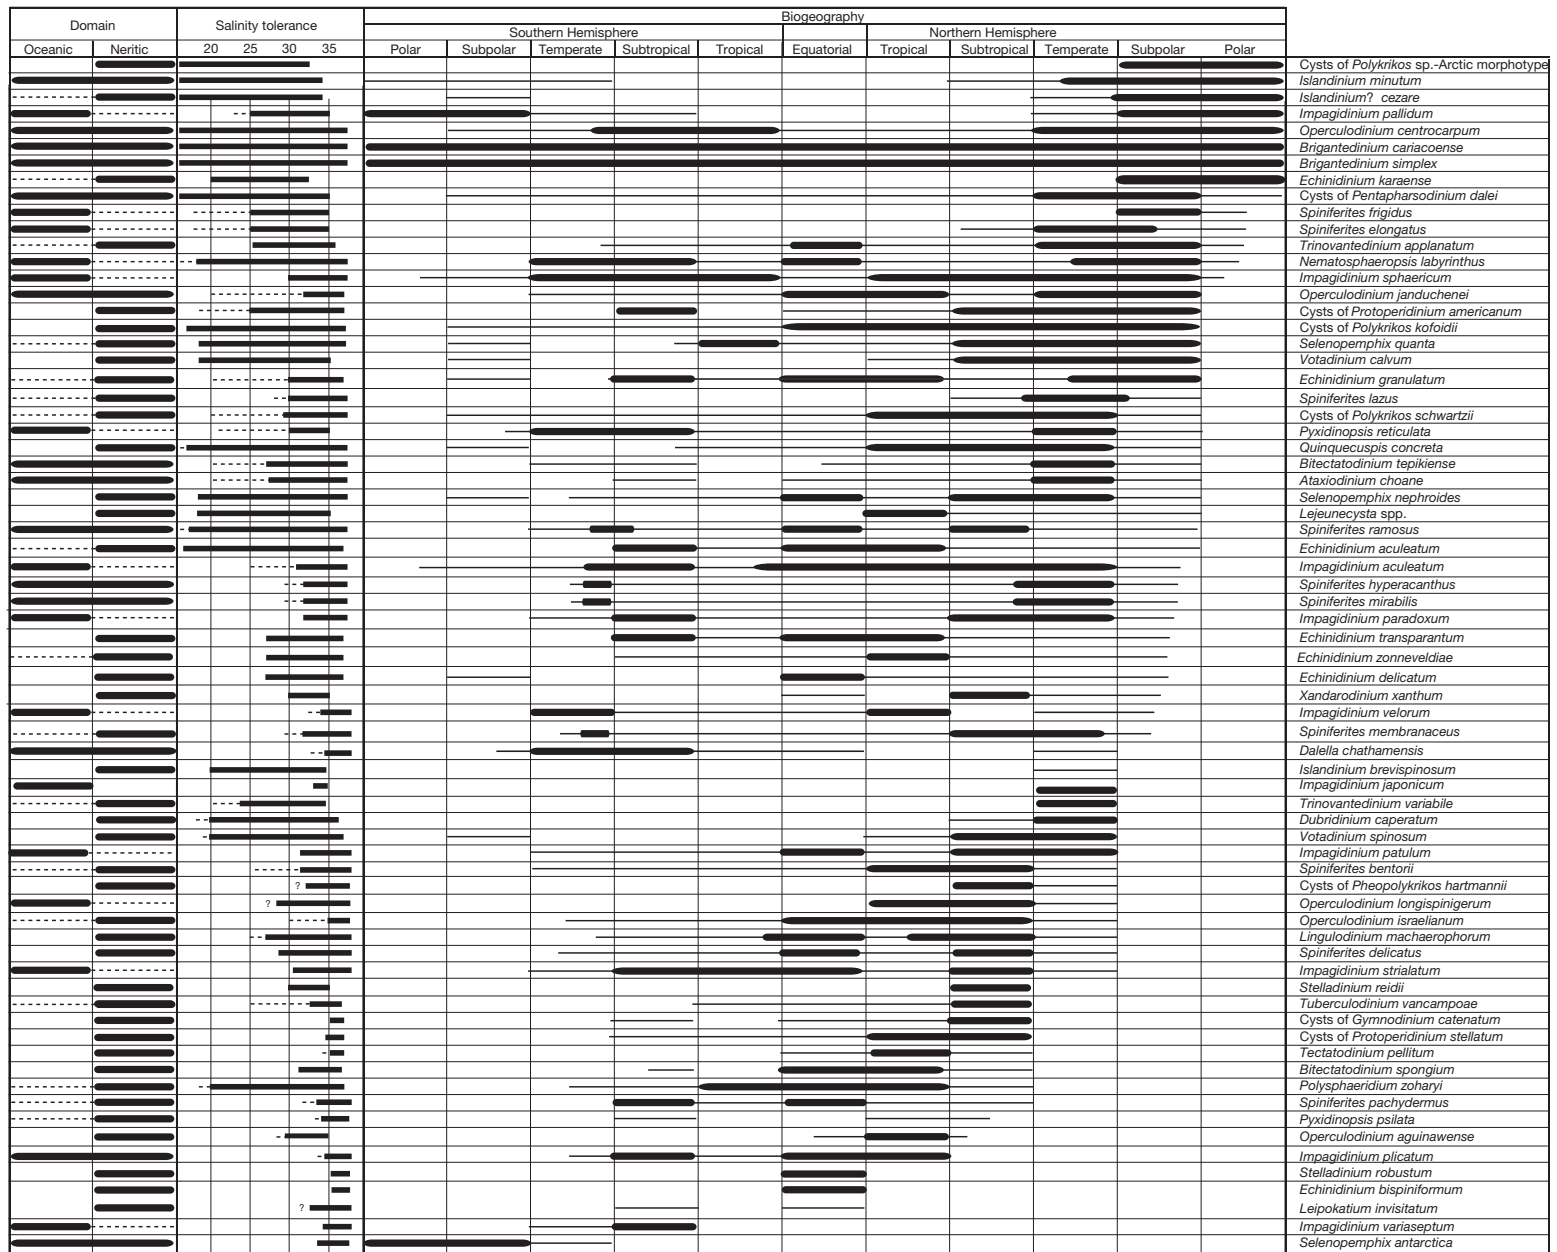

Figure 7 Latitudinal distribution of dinocyst taxa in surface sediments, salinity tolerance and neritic to oceanic occurrences (updated from Marret and Zonneveld, 2003; de Vernal et al., 2005; Radi and de Vernal, 2008).

Figure 8 Mean percentage of selected dinocyst taxa versus sea-ice extent in months per year with more than 50% of ice coverage. Note that most other taxa do not occur in areas characterized by seasonal sea ice (data updated from de Vernal et al., 2005 and Radi and de Vernal, 2008; see dinocyst databases at <http://www.geotop.ca>).

regional scales (subhemispheric ocean basins) also show relationships between the cyst assemblages and the sea-surface salinity, annual amplitude of sea-surface temperatures, sea-ice cover, primary productivity, and upwelling intensity (e.g., de Vernal et al., 2005, 2008; Radi and de Vernal, 2004, 2008; Rochon et al., 1999). At more local scales (estuarine systems), relationships with eutrophication can also be evidenced (e.g., Dale and Dale, 2002). However, because the composition of assemblages may vary significantly from a region to another, the quantitative relationships between dinocyst assemblages and hydrographic or oceanic conditions at regional or local scales cannot be extrapolated to a global scale (Figures 9–13).

Ecological–Paleoecological Significance of Dinocysts in Sediment

The dinocysts represent only a fragmentary picture of the original dinoflagellate populations (e.g., Dale, 1976; Head, 1996; Matthiessen et al., 2005). The ecological affinities of dinocyst taxa are known only by default, more from

distribution of the assemblages and species on the sea floor than from the ecology of their living counterpart. There are only few studies documenting the ecology of nontoxic dinoflagellates and the works coupling information on planktonic dinoflagellates and fluxes of dinocysts to the sea floor are extremely rare. Nevertheless, it seems that the biogeographic distributions of cyst-forming dinoflagellates in surface waters and that of dinocysts in sediments are generally consistent with each other (e.g., Dodge, 1994). There is a general consistency with respect to onshore–offshore patterns and latitudinal gradients, which closely relate to salinity and temperature controlled by current patterns. However, the correspondence between observations of motile and cyst assemblages is not perfect, notably due to the fact that the motile dinoflagellates in the plankton assemblages correspond to an instantaneous time interval, whereas the cysts in upper first centimeter of surface sediments may represent several years, decades or centuries of sediment deposition.

In paleoceanographic studies, dinocysts are usually associated with productivity in the upper part of the water column at

The scale bars on the photographs correspond to 10 μm . The circle diameter illustrates the cumulative percentage of the selected species in the dinocyst assemblages.

Figure 13 Photographs and distribution of selected dinocyst species of the genus *Polykrikos* (Order Gymnodiniales) in surface sediment samples from the Northern Hemisphere (updated from de Vernal et al., 2005; Radi and de Vernal, 2008). The scale bars on the photographs correspond to 10 μm . The circle diameter illustrates the cumulative percentage of the selected species in the dinocyst assemblages.

the site location. However, the sinking rate of individual cells or microscopic remains such as dinocysts is extremely slow (on the order of meters per day). Thus, incorporation within fecal pellets or marine snow (coherent aggregates of microscopic organic material having a density high enough to sink in the water column) constitutes mechanisms which likely explain the vertical fluxes of pelagic particles over hundreds or thousands of meters (e.g., Turner, 2002). Although dinocyst assemblages on the sea floor likely relate to sedimentation within marine snow and fecal pellets, some lateral transport with surface, intermediate or bottom currents, cannot be ruled out.

Dinocyst are made of refractory organic matter and usually preserve very well in marine sediments, unlike diatoms or foraminifers that are subject to dissolution of opal silica and calcium carbonate, respectively. From this point of view, dinocysts constitute an extremely useful proxy of ocean changes in many neritic environments and other regions of the world's oceans where calcium carbonate dissolution occurs because of a shallow lysocline and/or oxidation of organic rich sediments that fosters high pCO_2 . However, the cyst wall of some dinocyst taxa seems to be more susceptible to selective degradation when using strong oxidation techniques (e.g., acetolysis, KOH). Such techniques are occasionally used in palynology

but are avoided in the study of dinocysts. Good preservation of dinocyst taxa is generally assumed, although it is possible that selective degradation occurs in sediment or at the water–sediment interface under oxygen-rich conditions (cf. Zonneveld et al., 2001). The dinocyst taxa that are the most susceptible to degradation from oxidation are the cysts of *Protoperidinium* spp. and *Echinidinium* spp. (i.e., Peridinales taxa that are associated with heterotrophic productivity). These taxa are typically characterized by thin and brownish cyst walls.

Applications of Marine Dinocysts in Quaternary Sciences

Despite the caveats mentioned above, dinocysts constitute excellent tracers of sea-surface conditions. They are usually well preserved in sediments and the assemblages are characterized by relatively high species diversity, even in nearshore environments and in the Arctic and subarctic domains. From these points of view, dinocysts are complementary to calcareous microfossils such as planktonic foraminifers and coccoliths that are stenohaline (have narrow limits of salt concentration in water) and are used primarily in paleoceanography in the

low to middle latitudes. During recent decades, there have been increasing numbers of studies based on dinocysts in the field of Quaternary geology.

Hydrographic Reconstruction in Epicontinental Environments and Along the Continental Margin

In estuaries and marginal marine environments, dinocysts are particularly good proxies to document changes in sea-surface conditions, since they occur in a wide range of salinity and record both variations in salinity and temperature. Among dinocyst records from inland seas, the data from the Marmara and Black seas are particularly spectacular (e.g., [Mudie et al., 2002](#)) because the assemblages reveal extremely large salinity changes and because some taxa show morphological variations that reflect endemism that is likely due to isolation and low salinity ([Figure 14](#)).

In estuaries or deltaic environments, the various proportions of salinity-tolerant and stenohaline species can be used to estimate changes in salinity and freshwater discharges, for example off eastern coast of Canada, in the northwestern North Atlantic, or off Africa in the Equatorial Atlantic ([Bouimetarhan et al., 2009](#); [de Vernal and Marret, 2007](#)).

Paleoceanographic Reconstructions

The development of reference dinocyst databases from the studies of surface sediment samples has allowed the development of quantitative techniques for the reconstruction of sea-surface conditions such as temperature and salinity. Various attempts have been made to adapt regression and multiregression techniques (i.e., the conventional transfer functions), the best analog method or neural network approaches. Based on various trials, it seems that extrapolation approaches (neural networks and regression) that rely on calibration between the

assemblages and given oceanographical parameters strongly depend on the definition of the database ([Bonnet et al., 2010](#); [Guiot and de Vernal, 2007](#)). As a consequence, although extrapolation techniques may yield very good validation results, the reconstructions can differ significantly, depending on the calibration data set. Therefore, most paleoceanographic reconstructions from dinocyst data have been made on conservative grounds, using the modern analog technique that does not involve any extrapolation, but simply uses the similarity between the fossil spectrum and the modern assemblages to infer past sea-surface conditions (for a discussion, cf. [de Vernal et al., 2001, 2005, 2008](#)).

Quantitative reconstructions of sea-surface temperature, salinity and sea-ice cover have been made from many Quaternary sequences in the North Atlantic and data compilations are available for the Last Glacial Maximum (LGM), 21 000 years ago ([de Vernal et al., 2005](#)). In addition to significant changes in temperature, the dinocyst-based reconstructions point toward variations in the annual amplitude of temperature, and change in salinity and sea-ice cover ([Figure 15](#)).

Eutrophication, Productivity, and Upwelling

Dinocysts include fossil remains from both microzooplanktonic and phytoplanktonic communities. Thus, the dinocyst assemblages, together with the overall fluxes, depend on the primary productivity and the structure of the planktonic population. Studies from the fjords of northwest Europe, and along the coasts of Japan and America, have shown increased fluxes of dinocysts with higher percentages of heterotrophic taxa (cysts of *Protoperidinium* sp., notably). These changes in assemblages appear related to recent eutrophication, notably due to human activities. Some attempts have been made to distinguish the effects of eutrophication from those of pollution in dinocyst assemblages, but the results are equivocal (e.g., see [Dale and Dale, 2002](#)).

In ocean environments where upwelling results in high primary productivity and where the phytoplankton is dominated by diatoms, dinocyst fluxes are high and are characterized by the abundance of heterotrophic taxa over autotrophic ones (e.g., [Pospelova et al., 2008](#); [Radi and de Vernal, 2004](#)). Notably, downcore analyses performed off the African margin have shown variations in the abundance of Peridinales over the last hundred thousand years, which indicate changes in productivity and upwelling strength in relation to orbital forcing ([Figure 16](#); [Höll et al., 2000](#)).

Conclusion

Fossil dinocysts are mainly known from marine sediments and appear to be particularly abundant along continental margins (estuaries, continental shelves and slopes, epicontinental seas). Dinocysts have been widely used in biostratigraphy and paleoecology of the Mesozoic and Tertiary. In the field of Quaternary paleoceanography, paleoclimatology, and paleoecology, the study of dinocysts is of growing interest. Because they are very resistant to decomposition, dinocysts are generally well preserved in sediments, unlike the dissolution that

Figure 14 Photograph of *Spiniferites cruciformis*. Specimen from sediment collected in the Black Sea. Scale bar = 20 μm .

Figure 15 Example of late Quaternary dinocyst assemblages in the Labrador Sea, northwest North Atlantic, and corresponding reconstruction of sea-surface salinity, temperature, sea-ice cover, and mean annual productivity based on the modern analog technique. The figure shows the record from core HU91-045-094 (45°41.14 W 50°12.26 N; water depth = 3448 m). For more detail on the record, see for example, [Radi and de Vernal \(2008\)](#).

Figure 16 Example of dinocyst records representative of productivity and upwelling changes during the middle and late Pleistocene in the tropical Atlantic. The western site (core GeoB2204-2, 8°32'S, 34°01'W; water depth = 2072 m) is from a low productivity area and the eastern site (core GeoB1105-4: 01°40'S, 12°26'W; water depth = 3225 m) was collected in a productive upwelling region. In the sediments, the cysts of *Protoperidinium* spp. are associated with high productivity in surface waters whereas *Impagidinium* spp. are associated with oligotrophic conditions. The blue bands correspond to glacial episodes, which were marked by relatively high productivity in the eastern tropical Atlantic. Data redrafted from Höll et al. (2000).

may affect calcareous or siliceous biological remains. Moreover, the development of reference databases from surface sediment samples (e.g., Dale, 1996; de Vernal et al., 2001, 2005, 2008; Radi and de Vernal, 2008; Rochon et al., 1999; Marret and Zonneveld, 2003) has led to the documentation of strong relationships between the distribution of dinocyst assemblages and sea-surface parameters, including productivity and hydrographic conditions. Quantitative approaches, such as the best analog methods, have permitted the quantitative reconstruction of temperature, salinity and sea-ice cover extent. For example, hydrographic maps of the northern North Atlantic during the LGM have been established using dinocyst data, and many regional reconstructions are currently being developed. Other applications of dinocysts in Quaternary sciences include the reconstruction of hydrological changes from the study of cores collected in epicontinental seas or deltaic environments. Dinocyst assemblages may also provide insights into variation of the trophic character of upper water masses, leading to the identification of eutrophication in nearshore environments, and to estimations of changes in productivity in upwelling areas.

Introduction

The first genomic blueprint of a diatom confirms that diatoms evolved when a heterotroph, a single-cell microbe, engulfed a red alga. The two became one organism (endosymbiosis) and swapped some genetic material to create a new hybrid genome (Armbrust et al., 2004). Their origin, according to genetic and sedimentary evidence, must have occurred earlier than their first fossil record in the Jurassic. One possibility is that their origin may be related to the end-Permian mass extinction, after which many marine niches were opened.

Although individual cells are mostly in the size range of 10–200 μm , many planktonic diatoms form multicellular chains that can be several millimeters in length, occasionally exceeding a centimeter (Figure 1). Both benthic and planktonic forms exist, but because they are autotrophic (i.e., they photosynthesize carbohydrates in the presence of sunlight), they are restricted to the photic zone and are generally considered phytoplankton (photosynthetic organisms that live by floating in seawater).

Most species reproduce by mitosis, a process that repeats itself until a size threshold is attained. Then, they regain their size by auxospore formation. Cell division can occur every 4–8 h, leading to a billion cells in only 10 days.

Diatoms are formally classified as belonging to the division Chrysophyta, class Bacillariophyceae, and are divided in two orders: Centrales, radially symmetric, and Pennales, bilaterally symmetric (Figure 2). Their taxonomy is based on the form and ornamentation of their frustules, an advantage to paleontology since the same features can be used to define extant and extinct species (Hustedt, 1962). It is estimated that there are more than 200 genera and approximately 100 000 extant (living) species.

When nutrients and light conditions in the upper mixed layer are favorable, planktonic diatoms quickly dominate phytoplankton communities (bloom). As such, they are often ecologically classified as opportunistic r-strategists. In temperate continental shelves, a spring bloom occurs when sufficient light and nutrients are available. It is, however, in coastal, equatorial, and high-latitude upwelling regions that sudden population explosions occur. Upon depletion of nutrients, diatom cells typically increase in sinking rate or form resting spores (RS) and fall to the sediment (bust; Raymont, 1980; Figure 3).

Nitrogen has long been considered a limiting nutrient. However, genome work has revealed that some diatoms have a nitrogen waste pathway common to animal species that has never been seen before in photosynthetic organisms. This reduces their dependence on nitrogen from the surrounding waters. But what typically causes the end of diatom blooms is a lack of silicon (Si). Si is a major requirement for diatoms, and

it is not as efficiently regenerated as nitrogen or phosphorus. This is the reason why they play a key role in the regulation of the silicon cycle in the modern ocean.

Many species have special requirements, such as vitamins and micronutrients, which may explain the occurrence of high-nitrate low-chlorophyll (HNLC) areas in the ocean. Iron (Fe) enrichment experiments, both in culture and *in situ*, show a diatom growth response in a matter of days and reveal that Si drawdown by phytoplankton greatly exceeds that of nitrate, suggesting that Si is the ultimate limiting nutrient for diatoms under Fe-rich conditions in HNLC areas of the ocean (Peterson and Whitney, 2003). Fe limitation was also shown to increase the Si/C ratio and half Si/N and Si/P uptake by diatoms in HNLC regions, as well as increase the abundance of large diatoms that grow thicker shells. Coastal regions, always believed not to be limited by Fe, were also proved to have phytoplankton growth constrained by iron limitation (Hutchings et al., 2002).

The study of diatoms preserved/buried on the seafloor is of both economic and scientific interest. The economic interest comes from the exploration of diatomites, as well as from the fact that much petroleum is of diatom origin. Nevertheless, the most consequential activity of marine diatoms is their possible influence on climate. Oceans contribute about half of the global annual primary production (PP), a process by which carbon dioxide (CO_2) is converted into organic carbon and which is mostly carried out by phytoplankton (Falkowski et al., 2000). In modern oceans, diatoms are dominant in the high latitudes, and in equatorial and coastal upwelling regimes, the latter of which concentrate 80–90% of the ocean PP. This makes them the most important group of phytoplankton, responsible for almost half of marine PP. Due to their bloom-and-bust behavior, diatoms are believed to play a disproportionately important role in the export of carbon from oceanic surface waters (the biological pump). Moreover, Joint Global Ocean Flux Study (JGOFS) process studies support the hypothesis that highly productive areas are potential major centers of carbon sequestration. Furthermore, tests of marine diatoms growing under different CO_2 concentrations suggest potentially important biotic feedbacks as the level of global CO_2 increases and foresee a vital role for diatoms as mediators of global warming.

Paleoecology/Paleoceanography

Diatoms' small size and the fact that a high proportion of fossil taxa are still extant make it possible to use quantitative and statistical methods to attempt paleoenvironmental reconstructions from small samples.

Figure 1 Diatoms may be solitary free-living cells or attached to other cells to form many different types of colonies. (a) Chain colonies of *Thalassiosira nordenskiöldii* Cleve. Cells connected by mucilaginous threads; (b) single cell of *Planktoniella sol* (Wallich) Schütt; (c) single cells of *Corethron criophilum* Castracane; and (d) chain colonies of *Skeletonema costatum* (Greville) Cleve. Cells connected by marginal spines (<http://www.dnr.state.md.us/bay/cblife/algae/diatom>); (e) helical colony of *Chaetoceros debilis* Cleve; and (f) zigzag chain of cells of *Thalassionema nitzschoides* Grunow.

Methods

Quantitative methods

The first step is to start with a sample of known volume and weight so that diatom abundance ($\# \text{valves g}^{-1}$) and diatom accumulation rate (DAR: number of valves per cm^{-2} per ka) can be determined. The second step is the identification, to the most specific taxonomic level possible, of at least 300 individuals per sample. When diversity is high, the count number should be increased, as needed, to the level where no additional species are encountered.

The major problem faced by diatom paleoecologists is opal solubility. Silicon is undersaturated all over and all along the water column. After death and disintegration of the protective organic skin, opal frustules suffer dissolution during descent through the water column, on the sediment surface and during diagenesis. In the water column, regeneration rates depend on diatom type and bacterial assemblage, suggesting that regeneration is regulated by bacterial activity, which in turn depends on the initial physiological condition of the diatom

Figure 2 Example of arranged diatom slides made by naturalists in the late 1800s. These slides were traded worldwide and are still valued by collectors today. Note the radial symmetry in the Centrales diatoms and the bilateral symmetry in the Pennales. Slide from the collection of the Academy of Natural Sciences of Philadelphia. Photographs by Jane Rines. <http://thalassa.gso.uri.edu/flora/index.html>.

Figure 3 When conditions turn unfavorable, diatom cells typically increase in sinking rate and fall from the upper mixed layer. In the case of the genus *Chaetoceros*, this sinking is induced by the production of heavy resting spores (RS). (a) *Chaetoceros constrictus* Gran RS; (b) *Chaetoceros diadema* (Ehrenberg) Gran RS; (c) RS record of a bloom of *Chaetoceros* (www.marbot.gu.se/sss/ssshome.htm; photographs by Mats Kuylenskierna); and (d) a *Skeletonema costatum* record of a monospecific bloom. (c and d) are BSEI photos of Saanich Inlet laminated sediments. Reproduced from Dean JM, Kemp AES, and Pearce RB (2001) Palaeo-flux records from electron microscope studies of late Holocene laminated sediments, Saanich Inlet, British Columbia. In Bornhold BD and Kemp AES (eds.) Late Quaternary Sedimentation in Saanich Inlet, British Columbia, Canada-Ocean Drilling Program Leg 169S, *Marine Geology* 174: 139–158.

assemblage. On the seafloor, dissolution is mainly a function of the degree of Si undersaturation in the sediment pore waters and the rate of detrital accumulation, with small concentrations of Al inhibiting opal dissolution. Incorporation into fecal pellets or aggregates and the formation of heavily silicified RS tend to counteract dissolution. Trap studies have shown that in marine sediments, only 1–5% of the living assemblage in surface plankton is represented in the sediments. This selective dissolution results in the moderate enrichment of the sediments in resistant and robust taxa that are not important constituents of the water column or trap records. However, in coastal upwelling environments, most of the diatom taxa found in the water column and traps also occur in the sediment surface, as the dominant taxa are regularly maintained. Possibly because plankton taxa produced during blooms are preserved with greater efficiency than those produced during non bloom periods, and the dominant genus *Chaetoceros* Ehrenberg produces RS. Besides, relatively little lateral transport of diatoms during settling in the water column has been observed, and similar distribution patterns of the main species in the

plankton and sediment indicate that the diatom sedimentary record of productive areas can effectively be used for paleoecological inferences.

The lack of an effective and reliable method to quantify dissolution in the sedimentary record is still a problem. The use of a fragmentation index combined with the abundance of diatoms helps to identify samples marked by dissolution, but the best solution is the application of molecular marker techniques to identify the former presence of diatoms.

Diatom diversity, calculated on the basis of the Shannon–Wiener method, has also been used as an indicator of surface productivity, with low values indicating a near monospecific assemblage, as found in highly productive environments.

Sea surface temperature (SST) and PP are the two most likely parameters to reconstruct from this phytoplankton group: SST because diatoms record the true surface conditions and PP because diatoms are the most important primary producer in highly productive areas.

A first approach to calculate past SST was a temperature index developed through diatom modern biogeography

(Kanaya and Koizumi, 1966), using the temperature preferences of specific diatoms. The diatom-derived SST's qualitative index is still being used in Pacific Ocean studies and can indicate important trends.

A more quantitative approach to reconstruct past SST was pioneered by Imbrie and Kipp (1971) who generated a Foraminifera-based transfer function using factor analysis, followed by a multistep regression of factor loadings against SST measured *in situ*. In contrast to oceanic level reconstructions based on Foraminifera, better results are likely to be obtained from diatoms at the regional level and from regions/areas with great variability in the environmental parameter being reconstructed.

Diatom transfer functions (TFs) to estimate SST have been generated for the eastern equatorial Pacific, the North Atlantic, Antarctica, and coastal upwelling areas. While in the early years the Imbrie and Kipp approach was followed, more recent studies have included either linear or unimodal models, looking for which model best describes the ecological signal of the diatoms. The exploration of the relationship between diatom species and environmental variables using canonical correspondence analysis (for unimodal approaches) allows the development of TFs without having a predetermined environmental variable and taking into consideration the environmental variables' intercorrelations. This method puts considerable emphasis on the calibration and validation of the TF and allows past PP, salinity, and nutrient reconstructions, besides SST, for annual and several seasonal averages (Lopes et al., 2010).

To develop TF, it is imperative that the fossil assemblage is consistent with the assemblage on which the inference model is based. In order to minimize the effect of dissolution before burial, one attempt was made through the analysis of the fossil assemblages to which a set of surface samples partially dissolved in the laboratory was added.

Valve size

The diameter of *Azpeitia nodulifera* (A. Schmidt) Fryxell and Sims (formerly *Coscinodiscus nodulifer*) ranges from 10 to >100 μm . Diameter measurements in equatorial Pacific cores showed good correlation between maximum diameter and glacial periods. Since wind strength during glacial intervals intensifies oceanic circulation and generates stronger equatorial upwelling, larger forms of *A. nodulifera* may trace this increased upwelling. Another species that shows changes in valve diameter is *Paralia sulcata* (Ehrenberg) Cleve. In coastal environments, valve diameter appears negatively correlated to water column mixing, nutrient input, and PP rates. Temperature has also a positive effect on *P. sulcata* valve diameter, but in terms of salinity, conflicting reports have been published for different environments, reinforcing the idea that variations observed in the water column and/or the sediments should only be used as analogs on a regional/local level. More recently, a study by Crosta (2009) of size and abundance of two species, *Fragilariopsis kerguelensis* (O'Meara) Hustedt and *Fragilariopsis curta* (Van Heurck) Hustedt from East Antarctica Holocene sediments, supports the hypothesis that larger species populations reflect enhanced sexual reproduction.

Isotopic approaches

Isotopic and biomarker techniques have been developed that take into consideration the high dissolution potential of diatoms, as well as the possible winnowing and focusing of sediments, both of which may bias the quantitative and the assemblage data:

- $\delta^{18}\text{O}$ – Oxygen isotopes in marine diatoms should reflect seawater isotopic composition and temperature. Data obtained in eight deep-sea cores from the Antarctic–Atlantic sector revealed core-to-core consistency and similarity to the sequence of events recorded for glacial–interglacial cycles in standard Foraminifera-derived isotopic records, proving the utility of diatoms to generate much-needed $\delta^{18}\text{O}$ stratigraphies for the high latitudes (Shemesh et al., 1995). Generation of new $\delta^{18}\text{O}$ records has been limited by difficulties with the application of the technique, in particular with the obtaining of a clean and pure diatom sample, since even the cleaning methods can add oxygen from other components in the sample (Swann and Leng, 2009).
- $\delta^{13}\text{C}$ – The isotopic composition of carbon from organic matter enclosed within diatom frustules was proposed as a proxy for paleoproductivity and paleo-dissolved carbon concentrations in ocean surface waters.
- $\delta^{15}\text{N}$ – Nitrogen plays a role in the construction of the diatom silica frustules and represents an N archive related to the primary photosynthetic signal. Isotopic measurements of diatom $\delta^{15}\text{N}$ from the Southern Ocean (SO) surface nitrate pool and surface sediments reflect the proportion of nitrate supply from the subsurface that is consumed in the euphotic zone. Several downcore profiles of diatom-bound $^{15}\text{N}/^{14}\text{N}$ from the Antarctic show a consistent trend in the Indian sector but a marked contrast in Atlantic records (Robinson et al., 2004). The differences obtained with different measuring methodologies make it clear that more work needs to be done before the proxy can be broadly used.
- $\delta^{29}\text{Si}$ – Variations in the ratio of ^{30}Si – ^{28}Si in sedimentary opal have been proposed as a reliable proxy for past silicon cycle and diatom productivity. Seasonal variations detected in $\delta^{29}\text{Si}$ in the surface waters linked to upwelling events may also be of great use for paleo-upwelling reconstructions in the future.
- $^{231}\text{Pa}/^{230}\text{Th}$ – The preferential scavenging of opal by ^{231}Pa made the $^{231}\text{Pa}/^{230}\text{Th}$ ratio a possible proxy for opal paleoproductivity, at least in the Indian sector of the SO (Dezileau et al., 2003). Nevertheless, it is necessary to check if the measured opal is actually derived from diatoms.

Molecular Marker Techniques

Chlorine sterol esters (CSE) can be traced back to their biological precursors and are specific for each phytoplankton group. CSE sterols 3 and 4 are both derived by diatoms and have been proposed as a good marker for past diatom productivity (Dahl et al., 2004). Furthermore, long-chain diols and mid-chain hydroxy methyl alkanolates of diatomaceous origin were reported as indicators of high-nutrient conditions.

Proboscia laboratory cultures showed a strong relationship between long-chain diol and 12-hydroxy methyl alkanolate

composition with growth temperature; however, these results did not hold in nature (Rampen et al., 2009).

Finally, IP₂₅ (C₂₅ monounsaturated hydrocarbon), an organic compound believed to be produced mainly by diatoms living in sea ice, may prove to be a good paleoindicator of sea ice (Belt et al., 2007) and is now in the phase of global testing.

Trace metals

Diatoms incorporate trace elements in their opaline frustules. A Lake Geneva study indicates that the incorporation of different trace elements into the diatom frustules has substantially changed in consonance with climate state and the lake's ecological conditions (Jaccard et al., 2009), though the exact processes behind this correlation are yet unknown. In the ocean, several ratios using trace metals have been used as proxies for different parameters traced by the diatoms: in Antarctic sediments, the (Zn/Si)_{opal} ratio appears to be a proxy for the salinity of the mixed layer (Hendry and Rickaby, 2008). The Ge/Si ratio is used to study the Si cycle and climate change, as Ge mimics the behavior of Si in ocean: changes in the ratio mainly indicate changes in continental weathering, but the biological control (via diatoms) also appears to be important (Sutton et al., 2010).

Backscattered electron imagery

Backscattered electron imagery (BSEI) is used to study diatom-rich laminae and mats. The observation of polished thin sections produced from an undisturbed sample slab embedded in Spurr epoxy resin allows the visualization of diatom successions within individual laminae.

Diatoms and Oceanic Processes

Productivity

Glacial–interglacial variability

To verify the hypothesized diatom role in lowering atmospheric $p\text{CO}_2$ during glacial intervals, it is vital to develop a good understanding of past productivity conditions.
